SUPPLEMENT TO ENGINEERING NEWS, DECEMBER 31, 1896.

INDEX

TO VOLUME XXXVI, JULY-DECEMBER, 1896.

Subdivided into ILLUSTRATIONS; GENERAL (including *Editorials, Technical Articles, Current News* and *Correspondence*), and BOOK REVIEWS.
(Also CONTRACT PRICES of Supplement.)

INDEX TO ILLUSTRATIONS.

A.

- Air compressors, Jerome Park reservoir plant.... 205
- **Air locks, Zschokke & Terrier**.......... 318
- Angle-iron, Bridge, melted by lightning. 202
- Arches:
  - Centering, Suspended, Bordeaux...... 268
  - **Hinged concrete** *178
  - Melan, Atlantic Highlands, N. J...... 122
  - Niagara Gorge...... .... *82
  - Roof, Chicago Coliseum...... .. ....*306
- Axle box, Box car, B. & O. Ry.......... 196

B.

- Basket, Niagara gorge cableway, 1848.. 82
- Battleship, U. S., New.... ....*378
- Beacon tower, France.... 159
- Bending sheathing of quoin posts, **Apparatus for**. 84
- Block system for single track railways.. 247
- Boilers, Washington Mills.... ....*341
- Bolsters, Wood and iron, Freight cars..6, 7
- **Boring, drilling and milling machine,** Niles..... 269
- Borings, Diamond drill, East River...... 198
- Brake rigging, Box car, B. & O. Ry.... 196
- **Brake shoe, Freight car, B. & O. Ry**.... 197
- Brakes:
  - Bridge..... ....94, 95
  - Price momentum..... 261
- Brass melting furnace, Garrett.......... 219
- Breakwater, Buffalo, N. Y., New........ 284
- Brick mantle, Protecting river banks.... 299
- Bridge angle-iron melted by lightning.. 202
- Bridge brake.... ....94, 95
- Bridge floors, Concreted trough........ 18
- Bridge strains, Puzzle.... 127
- Bridges:
  - **Androscoggin River** 202
  - Atlantic Highlands, N. J., Melan arch. 122
  - Cernavoda, Danube River.... 130
  - Coulouvreniere, Geneva.... 91
  - Danube River..... ....130, *178
  - Draw, Harlem River, Third Ave...... 290
  - East River..... ....76, 77, 126
  - **Fairmount Park, Phil**... ....110, 111
  - French highway... 380
  - Harlem River, Third Ave......... 290
  - Highway, Trusses 199
  - Hinged concrete, Danube River.... ..*178
  - Hoosick Falls, N. Y.... 322
  - **Low-level, Queensland**...... 37
  - Merrimac, C. & N. Ry.... .... *18
  - Mira River, Nova Scotia.............. 430
  - Mirabeau, Paris.... ....316, 318
  - Newtown Creek, Brooklyn.......*292, 295
  - Niagara steel arch.... .... *82
  - Queensland, Low-level.... 37
  - Rock Island.... ....*406, 408
  - Rock River, C. & N. Ry.. .... *18
  - San Francisco & San Joaquin Ry....*274
  - Schuylkill River, Fairmount Park..... 13
  - Trusses for highway.... 199
- Bucket, Coal, Unloading plant......405, 406
- Buffer block, Cast iron.... ....*196
- Buildings:
  - **Astor Hotel, New York**.... ....*412
  - Niles Tool Works 45, 46
  - Park Row, N. Y. City... ......*226, 229

C.

- **Cableway,** Lidgerwood, Overhanging tower 333
- **Canal lock gates, Steel**................. 85
- Canal locks:
  - Great Kanawha River 98
  - Vertical lift, Heinrichenburg, Ger.....*150
- Canals:
  - **Fraser River, B. C**.................. 436
  - Mt. Nebo irrigation system........*354, 357
  - New York state 329
  - Nicaragua, Map 108
  - West Side Mining Co., Wyoming...... *66
- Car lighting. Moskowitz system......... 285
- **Car shops, Ill. Cent. Ry**...............*53, 55
- Car step, French adjustable............. 428
- **Car wheels, C., M. & St. P. Ry**.......... 155
- Cars:
  - Box, 60,000-lb., B. & O. Ry...........*196
  - Freight:
    - Bolsters, Wood and iron.............6, 7
    - Steel construction *6
  - **Garbage, Tacoma, Wash**.............. 22
  - **Loading structural material** 51
- **Catch basins, Hershberger**.............. 87
- **Centering for arches, Bordeaux**......... 268
- **Circle, Squaring the**.................... 108
- Coal dust stoker 295
- Coal unloading plant 405, 406
- **Coffer-dam, Great Kanawha River**...... 99
- Columns, Fire tests of...............92, 93
- Combustion, Diagrams 206, 207
- Compressed air plant, Jerome Park reservoir 205
- Concrete, Placing under water.......... 127
- Converters:
  - Bessemer 360, 361
  - Maryland Steel Co. 364
- **Conveyor, Hoover & Mason**............. 358
- Corn growing on sewage beds........... 166
- Counterweight systems for bascule bridges *292, 295
- Couplings for lead and iron joints....... 266
- Crane, Gantry 397, 399
- Current motor, Austin.................. 134
- Curves:
  - Spiral, for street railways............. 276
  - Transition, for street railways......59, 245

D.

- Dams:
  - Fishway for, Sterling, Ill.............. 123
  - Great Kanawha River.............426, 427
  - Mojave River, Cal.................... 158
  - Outlet gates, Mt. Nebo reservoir...355, 356
  - Pecos River, New Mexico 182
  - Pelzer, S. C. 34
  - Salt Lake City, Utah 258
- **Decarburizing cast iron in a reverberatory furnace** 359
- Derail. Gibbs' interlocking device....... 302
- **Derailing device, Alton, Ill**............. 437
- Derricks:
  - Compressed operation of.............. 205
  - Tower, Levering & Garrigues......... 394
  - Traveling, Byers 39
- Diagrams:
  - Appropriations made by Congress, 1885-95 52
  - Big Cottonwood Power Co., Available energy...... 221
  - Boiler covering, Insulating power..... 60
  - Columns exposed to heat 92
  - Combustion 206, 207
  - Foreign commerce of the U. S.......... 106
  - **Frog and switch values** 15
  - Indicator 69
  - Letters, Speed of forming............. 79
  - Locomotive weights 13
  - Retarders and fuel saving 60
  - Speed of Allis engine 252
  - Stresses in compression members...... 253
- Drawing table, Pen-Jay................ 78
- **Drying and heating plant, Cummer**...... 36
- Dynamos, Westinghouse, Niagara Falls.. 389

E.

- Electric light plant, Johnson, Vt........ 233
- Electric power:
  - **Fresno, Cal., Pipe line**................ 12
  - **Niagara Falls** 388, 389
  - Pelzer, S. C. 34
  - **Salt Lake City, Big Cottonwood plant**.*220
- Electric railways:
  - "K. A. K." conduit system............ 31
  - Third rail system 268
- Elevated railways, Chicago:
  - Interlocking 125
  - Terminal loop 46
- Engines:
  - Chapman's link movement.............101
  - Direct connected 142. *254
  - Gas, Lorois 262, 263
  - Naphtha, "Simplex" 315
  - Raworth direct driving.............. 142
  - (See also **Hoisting engines**.)
- Excavation by compressed air.......... 206

F.

- Feed-water regulator, Automatic........ 219
- **Ferry house, Barclay St., New York**.... 103
- Ferry steamer, Screw propelled........ 335
- Filter beds:
  - Corn growing on.................... 166
  - Lambertville, N. J., Construction...... 4
- **Filters, Warren, Reading, Mass**......... 348
- Fire, Effect of, Steel-frame factory...... 5
- Fireproof material, Apparatus for testing. 92
- Fireproof wall, Ferry house............ 103
- Fishway for dam 123
- Floors:
  - "Chicago" fireproof 23
  - Concreted trough for bridges......... 18
  - McCabe concrete 319
- Floors. (Continued.)
  - Rapp system 286
  - Thomson concrete 319
- Flumes, Mt. Nebo irrigation system..356, 357
- Flushing device, Sewer, Bridge......... 90
- Foundations, Concrete, Molds for....... 127
- Foundry, Niles Tool Works............45, 46
- Freight cars:
  - Bolsters, Wood and iron 6, 7
  - Steel construction *6
- Frog and switch values 15
- Frog, Spring rail, Pacific Rolling Mills.. 339
- **Furnace, Garrett brass-melting**.......... 219

G.

- Gaging sewage flow, Apparatus......... 165
- Garbage cars, Tacoma, Wash........... 22
- Garbage crematory, Portland, Ore....... 125
- Garbage disposal plant, Cin., O......... 236
- Garbage scows, Seattle and Tacoma, Wash... 22
- Gas engine, Lorois 262, 263
- Gate valve, Hydraulic power 138
- Gold washer *66, 67
- Grain handling apparatus 325
- Gun, Savage rifle 52

H.

- Hammer, Vulcan-Nasmyth 38
- Harbors, Chicago 41
- Hoisting and conveying apparatus, Temperley 47, 48
- **Hoisting engines:**
  - **Anaconda Mining Co**...... ......146, 147
  - **Hunt** 438
- Hoisting plant, Ashtabula, O............ 114
- Hydraulic ram, Rife.................... 429

I.

- Indicator diagrams 69
- Injector test, Apparatus for............ 39
- Insets:
  - **Astor Hotel, New York**...............*412
  - Battleships, U. S., New *378
  - Boiler plant, Washington Mills........*341
  - Bridges:
    - Hinged concrete *178
    - **Newtown Creek, Brooklyn** *292
    - Niagara steel arch *82
    - Rock Island *406
    - Rock River and Merrimac........... *18
  - **Building, Park Row** *226
  - Canal lock, Heinrichenburg *150
  - Canal, West Side Mining Co.......... *66
  - Cars:
    - Box, B. & O. Ry...................*196
    - **Steel** *8
  - Park Row building *226
  - Railway, Siberian *322
  - Reciprocating parts for locomotives.... *99
  - Reservoir, Mt. Nebo..................*354
  - Roof arches, Chicago Coliseum........*306
  - San Fran. & San Joaquin Ry. structures *274
  - Shops, Ill. Cent. Ry...........*34, *53, *55
  - Steam engines, Direct connected......*254
  - Track elevation, Chicago......... ....*114
  - Turntable, Greenleaf *174
  - Water power electric plant, Salt Lake City *220
  - **Water supplies:**
    - Colorado Springs *131
    - Salt Lake City *258
- Insulating rails, Device for............ 135
- Interlocking, Chicago elevated railways.. 125
- Irrigation, Mt. Nebo system, Utah..*354, 357

J.

- Journal bearing, Anti-friction........... 178

K.

- **Keyseater, Portable, Burr**.... 218

L.

- Letters, Relative speed of forming different alphabets 79
- Lighthouse, France, at Trois Pierres..... 159
- Link movement engine 101
- Loading structural material on cars..... 51
- Locks, Canal:
  - Dortmund and Ems canal.............*150
  - **Great Kanawha River** 98
  - **(See also Air locks.)**
- Locomotive counterbalancing:
  - Diagram 13
  - Reciprocating parts, Light-weight..... *99
- Locomotive shops, Ill. Cent. Ry........ *34
- Locomotives:
  - **American, for foreign railways**........ 194
  - Baldwin compound 50, 194
  - "Schenectady," Sections of........206, 207
  - **Stevens valve gear** 419
  - Tank, P., C., C. & St. L. Ry........... 342
  - Two-cylinder compound, Austria...... 379
  - Wheel flanges, Thickness............. 19

M.

- Macadam roadway 385
- Maps:
  - Big Cottonwood River *220
  - **Chicago elevated railways** 46
  - Chicago harbor 41
  - Den. & Rio Grande Ry., Profile....... 242
  - Guatemala Northern Ry.............. 14
  - Mojave River, Cal................... 158
  - Mt. Nebo irrigation system........... 354
  - Nicaragua canal 108
  - Pecos Valley irrigation system........ 181
  - Railways near Atlantic City.......... 89
  - **Salt Lake & Mercur Ry**............... 2
  - San Diego, Cal., water supply......... 83
  - **Seattle, Wash., Tide-flat filling**........ 436
- Meters, Water, Torrent................ 78
- Motor, Current, Austin................ 134

N.

- Niles Tool Works, New foundry........45, 46

O.

- Ore-handling plant, Ashtabula, O........ 114

P.

- Pavement, Brick, Cortland, N. Y........ 160
- Paving for street railway track.......... 251
- Photograph used in topographic survey. 331
- **Pier, Stone-filled concrete** 396
- Pile hammer, Vulcan-Nasmyth.......... 38
- Pipe line and power house, Fresno, Cal.. 12
- Pipe scrapers, Automatic.............. 141
- Piston, Cast steel, Pacific Rolling Mills.. 340
- Planimeter, Lippincott 410, 411
- Plank driven through plate girder...... 43
- Plow, Mechwart rotary 403, 404
- Pneumatic tires for vehicles............ 214
- **Pole line, Niagara Falls to Buffalo**..... 390
- Power houses. (See Electric power.)
- Press, Dick hydraulic.................. 70
- **Profile of Den. & Rio Grande Ry**....... 242
- Pumping engine, Sewage, Norfolk, Va... 421
- **Pumping station for fire protection**.... 422
- Pumps, Centrifugal, Richards........... 11

Q.

- Quay wall, Iron and concrete 21

R.

- Radiators in boiler tubes 61
- Rail fastening, Screw spike 58
- Rail sections:
  - C., M. & St. P. Ry 155
  - Denver & Rio Grande Ry. 157
- Rails:
  - Insulating, Device for................ 135
  - Street railway:
    - San Francisco 339
    - Wear in 278
- Railways:
  - **Atlantic City, N. J**.................. 89
  - Chic. & North., Track elevation......*114
  - Guatemala Northern, Map............ 14
  - Salt Lake & Mercur.................. 2
  - Siberian *322
- Ram, Hydraulic, Rife.................. 429
- Rapid transit railway, New York....309, 311
- Reciprocating parts for locomotives..... *99
- Reservoirs:
  - Mt. Nebo, Utah *354
  - Oakland, Cal., Failure 301
  - York, Pa., Section of................ 151
- Rifle, Savage..... 52
- River outlets on Lake Huron........... 128
- River regulation 128

Illustrations marked * are printed on inset sheets.

Wagon. Mail-collecting and storing 144
War department estimates 257
Warship on a street railway 410
Warships:
"Annapolis" launched 440
Bids for new 1, 17, 199, 209
Boiler rooms, Temperature 416
"Brooklyn:"
Description of 113
Trial speed 161, 204
Coal consumption, U. S. Navy 320
Compressed air for operating .. 257, 264, 337
English, "Spitfire," Speed 209
Failure of steel plate 415
"Hannibal," Dimensions 3
Holland torpedo boat 129, 320
"Iowa," Trial 337
Japanese, built in U. S 319
Latest American battleships 378
"Newport" launched 391
"Puritan" completed 209
Russian "Kherson," Speed 1
Smokestacks, High 33
Submarine torpedo boats, Design for French 16
"Terror," Pneumatic plant 337
"Texas," Grounding of 296, 305, 423
"Vicksburg" launched 391
Water, Ownership and control in the Irrigable West 365, 402
Water analyses:
Bacterial, Beaver Falls, Pa. 117
Chemical:
Beaver Falls, Pa 116
Reading, Mass. 350
Water-bearing gravel, Test, Beaver Falls. 116
Water companies:
Charter, Forfeiture of 126
Injunction against 126
Regulations of 44

EDITORIAL:

The Construction of Steel Cars. 8
LETTER TO THE EDITOR 10
—Garbage Disposal in England.

TWO FAST TRANSATLANTIC RUNS were finished on June 26 by the "St. Paul," of the American Line, from Southampton, and the "Lucania," of the Cunard Line, from Liverpool The "St. Paul" made the course of 3,113 miles in 6 d. 8 h. 19 min., or at an average speed of 20.44 miles per hour, the daily runs being 457, 507, 498, 489, 515, 540 and 103 miles, while the vessel's highest record is 6 d. 5 h. 32 min., with a maximum daily run of 522 miles. The "Lucania" made the course of 2,855 miles from Queenstown in 5 d. 13 h. 35 min., or at an average speed of 21.30 miles per hour, the daily runs being 96, 524, 529, 507, 542, 562 and 95 milets, while this vessel's highest record is 5 d. 7 h. 23 min. The "Lucania" has engines of 30,000 HP., consuming 540 tons of coal per day; while the "St. Paul" has engines of 20,000 HP., consuming 315 tons of coal per day.

◆

THE RUSSIAN TRANSPORT "KHERSON," on its recent trial trip made an average speed of 19.6 miles per hour for 12 hours, the engines making 90 revolutions per minute. The vessel resembles an ocean steamer, and is 500 ft. long, and 54 ft. 3 ins. beam, with a gross tonnage of 6,000 tons. It has twin-screw engines and three batteries of Belleville water-tube boilers. The armament will include three rapid-fire rifled guns and 20 small guns.

◆

A BALLOON TRIP TO THE NORTH POLE is to be attempted by Mr. Andree,a French aeronaut, who expects to start from Spitzbergen about the end of June. The balloon is nearly 70 ft. high, and the basket is 6 ft. diameter and 5 ft. high. Two persons will accompany Mr. Andree, one of whom will be a photographer. Steering sails are fitted above the basket, and the balloon will also be steered by a long drag rope trailing on the ground, which can be hitched to any part of the ring of the balloon. When the long guide rope is trailing heavily in the snow below, at right angles to the plane of the sail, the wind will strike the sail in full and the balloon will go straight ahead before the wind. But when the upper end of the rope is shifted to any position on the ring desired, thus deflecting the strain, which can easily be done by means of an apparatus constructed expressly for that purpose, then the balloon will be compelled to shift its position, thereby placing the sail at an angle with the wind, which must result in changing the direction of the balloon. That it will do this is said to have been proved by an experimental trip.

◆

A CURIOUS BOAT, which is, of course, to revolutionize ocean navigation, has been built by Peter Beckman, of Bucksport, Me. A horizontal cylinder, 10 ft. diameter and 13 ft. long, closed at the ends, except for a hole at the axis, has floats or buckets 8 ins. wide and 24 ins. apart, attached to the outside, and is driven by gearing on the inside. This big paddle wheel has a superstructure for decks and is intended to roll along the water. The idea is old, but as the builder of this particular craft has no pretensions to mechanical knowledge, he probably considers it both new and good.

◆

MAKING FLYING SWITCHES is said by the New York State Board of Railroad Commissioners to be not a dangerous practice. This was in answer to a complaint against the practice by which the engines of passenger trains approaching the Grand Central terminal station in New York are switched off in front of the train, the engine being uncoupled and running ahead of the train. This decision is about on a par with the board's statement to the effect that radially stayed fireboxes are specially dangerous, which statement was discussed in our issue of June 18.

◆

ELEVATORS AT RAILWAY STATIONS have been applied at many large terminal stations where the tracks are elevated above the street level, and have recently been installed at the terminal station of the Lake St. Elevated R. R. in Chicago. There are two electric elevators, each accommodating 20 passengers, and running at a speed of 120 ft. per minute.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred on the Chicago, Milwaukee & St. Paul Ry., near Davis Junction, Ill. A car in the middle of a freight train jumped the track and was run into by a fast freight going in the opposite direction on the second track. Thirty-five cars were wrecked, one man was killed and two injured. The wreck caught fire and burned.

◆

A LOCOMOTIVE BOILER EXPLOSION occurred on the New York Central R. R., June 23. The engine was backing a local train onto a sidetrack at Utica, N. Y., when the boiler burst. The engineman was killed and the fireman seriously injured.

◆

A MINE DISASTER in which a large number of men, estimated at nearly 60, have lost their lives, occurred at Pittston, Pa., on June 28. The men were at work about 100 ft. from the surface. The mine had shown signs of caving for several days and a large extra force had been put to work on the timbering. Work of rescue is in progress, but the great extent of the cave and successive falls have made it impossible to reach the buried men.

◆

HE LOSS OF THE STEAMER "Capulet" occurred on the coast of Newfoundland, June 22. The vessel was bound from Halifax to Liverpool, and struck on the rocks in St. Mary's Bay in the afternoon, during a thick fog, the vessel being about to touch at St. John's to land the mail. The crew and passengers got off in the boats, and were picked up by a fishing schooner.

◆

THE PARTITION OF A WATER POWER is a question which has just been brought before the Supreme Court of Iowa. The water power in question is located at Cedar Rapids and a suit for its partition was brought some time ago. Mesrs. Clemens Herschel, of New York, Prof. Williams, of Mt. Vernon, Ia., and Samuel Sherwood, of Independence, Ia., were appointed referees by the court. They presented a report setting forth that an actual partition or division of the property into the required fractional parts was impracticable without an indefinitely continuing intelligent operation and supervision of the appliances that might be erected, and that in their judgment a sale of the property and a division of the proceeds was the only practicable method of partition.

Exceptions were taken to this report and were sustained by the court, and afterwards J. T. Fanning, W. P. Clark and A. H. Conner were appointed referees to make partition in kind, and recommended the erection of adjustable weirs so as to measure out to each owner the share of water to which he was entitled. They also recommended that the court direct the owners of the property to employ a competent inspector of the weirs who should, as often as necessary, see that they were kept in proper adjustment and repair.

The lower court approved this finding and an appeal was taken to the Supreme Court. That body now decides that this is not a case where there can be a fair division of the property in kind. The only way in which partition can be made is to sell the property and divide the proceeds.

◆

A BID FOR CAST-IRON PIPE at a recent water-works letting at Petrolea, Ont., was submitted by an Alabama firm at a price lower than the bid of any Canadian foundry, notwithstanding the duty of $10 per short ton and the long freight haul. About eleven miles of 12-in. force main and 7½ miles of 12 to 4-in. distributing mains are included in the contract, which was finally awarded to Carson & Co., of St. Catherines, Ont., who put in a lump bid for the whole plant, except pumps and filters.

◆

THE LATEST PHILADELPHIA WATER SUPPLY scheme is said to be as follows: The Philadelphia Water Supply Co. offers to furnish filtered Delaware river water for a period of 50 years for 60% of the gross revenue of the city water-works, based on present rates. The details of the scheme are rather mixed in the newspapr reports at hand, but these state that there will be two 11-ft. steel conduits, one 21 and the other 80 miles long. The latter would take water from the river above Easton, and the former at a point six miles above Trenton.

◆

A SUIT FOR HYDRANT RENTAL brought by the Peoria Water Co. against the city of Peoria, Ill., has been decided against the company in the Appellate Court of Illinois, where the decision of the Circuit Court was affirmed. The suit was for some $13,500, something over a quarter's charges for water used for public purposes. The court held that under the franchise the contract is a yearly one, and that since the bonded indebtedness of the city exceeded the constitutional limit, without an obligation for water for 1895, none could be legally incurred. This decision has no bearing upon the validity of the company's franchise, but seems to leave the city powerless to secure water for public purposes until its debt is reduced, unless it secures the necessary money by taxation in advance. The decision also seems to affect other branches of the municipal service.

◆

A RIFE WATER RAM or hydraulic engine at Rondout, N. Y., on the Ulster & Delaware R. R., delivers 900 gallons of water per hour at an elevation of 47 ft. 6 ins., through 580 ft. of 2½-in. pipe, the driving stream flowing through a 4-in. pipe having a fall of 9 ft. 6 ins. in 33 ft. 6 ins. The machine is used to supply a locomotive supply tank.

◆

COMMISSIONERS TO PROVIDE a new water supply for Cincinnati have been appointed by the Governor of Ohio, as follows: Messrs. August Hermann, Leopold Markbreit, C. M. Holloway, Dr. T. W. Graydon and Maurice J. Freiberg. Mr. Herrmann is, or was at the time of his appointment, a member of the Board of Administration, which has charge of the water-works. He has been elected president of the commission. The estimated cost of the proposed new supply is about $6,000,000. Injunction suits have already been filed to test the legality of the act under which the appointments were made. One of the principal points of attack is that the act is special legislation, as Cincinnati is the only city in the state which could possibly come under its provisions.

◆

BIDS FOR BATTLESHIPS have been invited by the Navy Department at Washington. The specifications call for three battleships each of 11,000 tons displacement and each to cost $3,750,000 exclusive of armament. Bids may be offered in two ways: On the plans furnished by the government, or on plans furnished by the bidder. The speed to be maintained at sea for four consecutive hours is to be not less than 16 knots per hour. For failure to attain this speed $25,000 for each quarter-knot deficiency shall be deducted from the contract price, and if the speed falls below 15 knots the vessel may be rejected. The department is also inviting bids for 13 torpedo boats, the fastest of which shall maintain 30 knots per hour.

THE SALT LAKE & MERCUR RAILROAD.

By W. P. Hardesty, C. E.

The Salt Lake & Mercur Railroad is a standard-gage mountain road, for giving the Mercur mining camp connection with the railway system of Utah. This camp is situated in Camp Floyd Mining District, in the Oquirrh Mountains, and near the center of the State. This district has, within the past two or three years, attracted a great deal of attention, on account of the discovery and working of enormous bodies of gold-bearing ore, so that within the past few months it has been enjoying a veritable western mining boom. The gold found is not free-milling, not the usual "quartz" gold, but is in a form that requires the application of the cyanide process to secure it. The town of Mercur is the site of the first developments of the gold mines and is the commercial center of the district. It lies just over the divide, and on the west side of the Oquirrh range, which divides Tooele County on the west from Utah County on the east.

The Tintic branch of the Union Pacific Ry. traverses Cedar Valley on the east side of the range, and from the station of Fairfield, which is 49 miles from Salt Lake City, the Salt Lake & Mercur R. R. is built to the Mercur Camp.

The Oquirrh main range, though not high, is difficult to surmount on account of its slopes rising abruptly to its narrow summit, it having no considerable mountain streams with their canons, and it is entirely different in these respects from the Wasatch range of mountains.

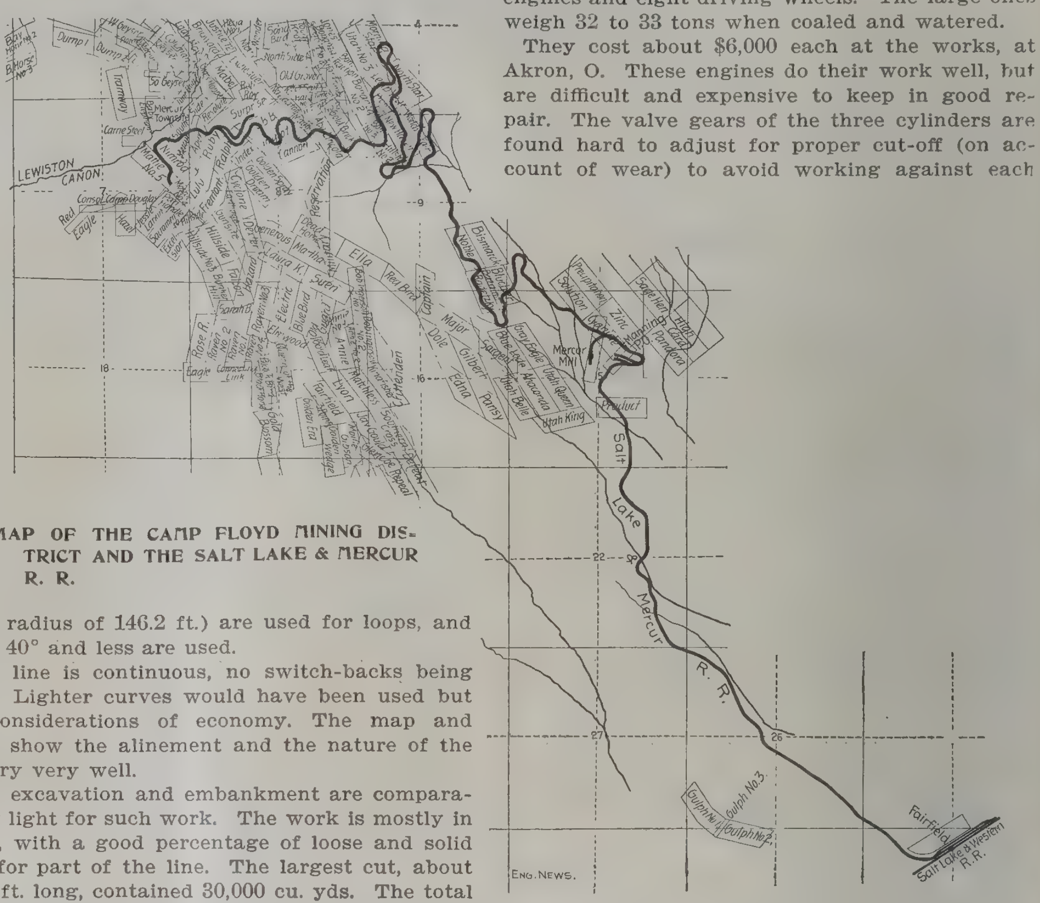
From Fairfield to Mercur the distance in an air line is 6 miles. The Salt Lake & Mercur R. R. Co. was organized to build this road. Col. Chas. D. Moore, who has had an extensive experience on the location and construction of western railways, was selected as chief engineer, and work commenced in July, 1894.

A large gulch comes down from Mercur divide on the east side of the range and opens out into Cedar Valley, directly opposite Fairfield station. Up the general line of this gulch the road is located. From Fairfield to the mouth of the gulch the distance is 4¼ miles by the line. The road is fairly straight and direct from this portion, and an average ascending grade of 3.75% is used, with a maximum of 4.2%. Then the development begins.

A STATION ON THE SALT LAKE & MERCUR R. R.

Here at the mouth of the gulch are located the shops of the Salt Lake & Mercur R. R., and also the Mercur mill, for reducing the ores of the famous Mercur mine. The station here is called Manning. From Fairfield to Manning the rise is 844 ft.; from Manning to the summit the rise is 1,142 ft. more, in a direct line of less than 2½ miles, and by the railway of 5⅓ miles.

The total elevation overcome from Fairfield to the summit (called Mercur divide) is 1,986 ft., the length of line 9.58 miles in a direct distance of less than 5½ miles. The maximum grade used is 4.2%, and the maximum curvature 42°, the grade being equated for curves at the rate of .02% per degree. Six of these sharp curves (having a radius of 146.2 ft.) are used for loops, and many 40° and less are used.



MAP OF THE CAMP FLOYD MINING DISTRICT AND THE SALT LAKE & MERCUR R. R.

The line is continuous, no switch-backs being used. Lighter curves would have been used but for considerations of economy. The map and views show the alinement and the nature of the country very well.

The excavation and embankment are comparatively light for such work. The work is mostly in earth, with a good percentage of loose and solid rock for part of the line. The largest cut, about 1,000 ft. long, contained 30,000 cu. yds. The total cost of grading was about $30,000.

There are four 45-ft. culverts for crossing main gulches. But little trouble with either wash-outs or snow has been experienced in the operation of the line. Standard ties are used throughout. 35-lb. second-hand rails were put down. These are to be replaced on the east side of the summit during the summer of 1896 by new 52-lb. rails, the old ones being used for the extension and switches on the west side.

The rails were elevated on curves for a speed of 12 miles per hour. The gage was not widened on curves, Col. Moore deeming it a disadvantage to do so under the conditions here, and of little benefit in any case.

The railway cost, fully equipped, about $75,000. Shay geared locomotives are used, it of course being impracticable to use ordinary mountain engines on such a road. There are one 18-ton and two 28-ton Shay locomotives in the service, the former being geared 3 to 1 and the latter 2 to 1. Each locomotive has three cylinders or engines and eight driving wheels. The large ones weigh 32 to 33 tons when coaled and watered.

They cost about $6,000 each at the works, at Akron, O. These engines do their work well, but are difficult and expensive to keep in good repair. The valve gears of the three cylinders are found hard to adjust for proper cut-off (on account of wear) to avoid working against each other. The wheel base of the small engines is 47 ins., of the large ones 52 ins.

The ore cars used by the road are 30 ft. long, weigh 20,000 to 21,000 lbs., and have a rated capacity of 15 tons, though 18 to 20 tons are often carried. The 34-ft. box cars of the Union Pacific Ry. are hauled over the line with no trouble at all. At one time a 46-ft. furniture car was also taken up to Mercur. It is found that any wheel base of over about 6 ft. 8 ins. gives trouble. The sharp curves, unless reversed, do not seem to affect train motion to any appreciable extent. The ability of the cars to stick to the track seems to depend mostly on their ease of swiveling on their trucks.

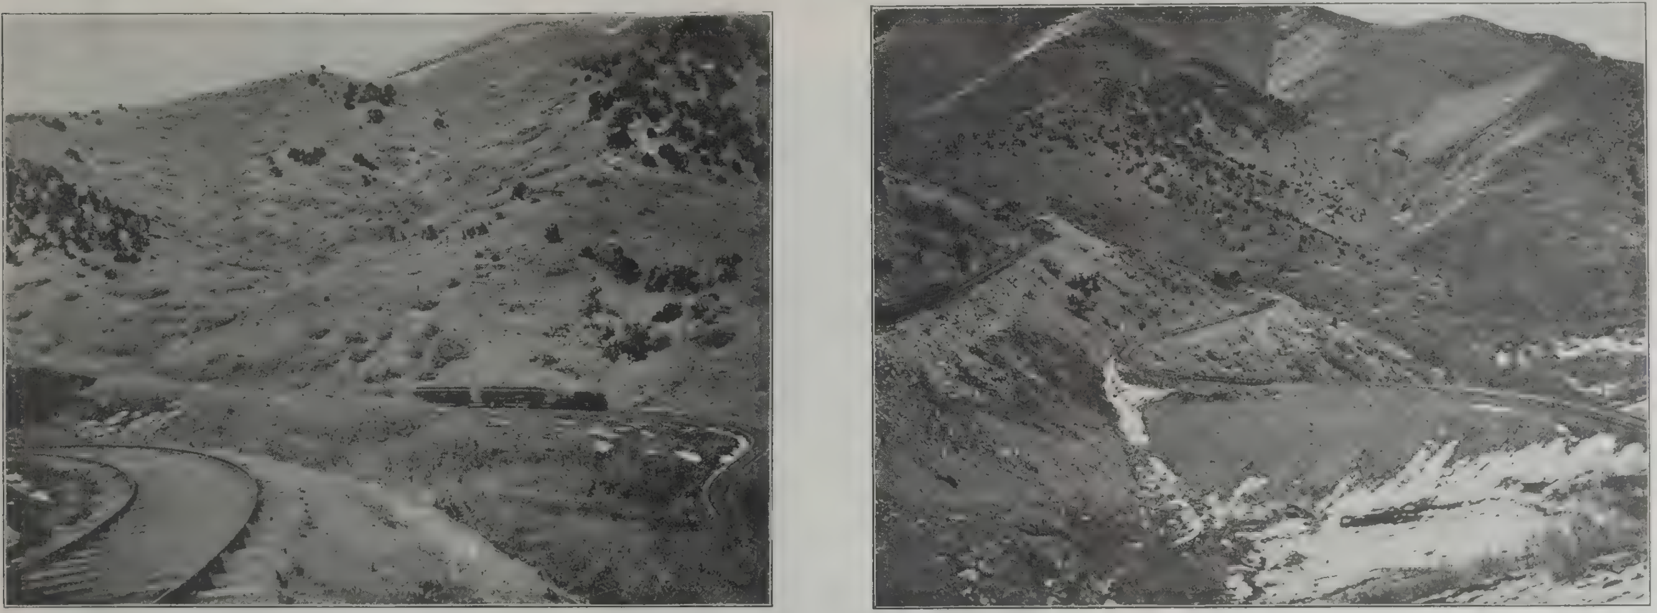
At one time a car got loose and ran for three miles, presumably at 40 or more miles per hour, before being ditched by a broken rail. At another time one got loose and was derailed by the workmen hurrying down the hill-side and placing a tie across the track, catching the car in its return down a loop.

For down trips an air pressure of 20 lbs. is kept on the drivers of the engine, and is applied to the cars only for stops. All cars are equipped with Westinghouse air brakes and with hand brakes. The water brake is not used with the Shay engines, as it is thought that there would be a possible danger of their cogs stripping if it were. Chilled steel brake-shoes are used and are worn out very fast.

On up trips two passenger coaches or three box cars is counted a fair load, while seven empty ore cars are taken up at one trip. Mercur station is located nearly one mile further and 132 ft. lower than the summit, being 10½ miles from Fairfield. The depot is 253 ft. higher than the center of the town, which lies in the bottom of Lewiston Canyon. An extension of the road is now being built that will get down into the town on a comparatively easy grade, with a distance of about two miles. This requires extensive development, and two switch-backs are also used. The grade on the west side of the summit is all 2.4% descending, except one level portion of 500 ft.

The operation of this road has proved very profitable, and has fully justified the enterprise of the projectors. An average of 200 tons of ore per day are carried from the Mercur mine to the Mercur mill at Manning, at a contract rate of 35 cents per ton. With a number of other mines that have about begun shipping, the revenues from these sources may greatly increase. A considerable business is also done carrying miscellaneous freight and passengers, high rates being charged. The road has been in operation since January 20, 1895.

The only other road of any importance in Utah that exceeds the Mercur road in heaviness of grades is the Utah Central, running from Salt Lake City to Park City, distant 31.6 miles. This road has 6% and 6½% grades for considerable of its length, and one very short strip of 7¼%; while 4% and 5% grades are very common.



VIEWS ON THE SALT LAKE & MERCUR R. R. IN UTAH. MAXIMUM GRADE, 4.2 %; SHARPEST CURVE, 42°. ELEVATION OF 1,986 FT. ATTAINED IN A DISTANCE OF 9.58 MILES.

It has three switch-backs, however, and moreover is exceedingly difficult and expensive to operate, both on account of the heavy grades and because of snow, being located on the wrong side of the valley it traverses. It is a narrow-gage road, with maximum curvature of about 20°. It runs over the Wasatch Mountains, following up the valleys of Parley's Creek and its forks.

By a proper location, using more distance, the grade could have been kept down to 4%, giving a line with better ground for construction as well as much more freedom from snow.

The summit of the divide crossed by this road (19 miles from Salt Lake City) is 7,046 ft. above sea-level, that of the Mercur divide being nearly as high. The Utah Central road, with an engine weighing 40 tons without tender and something like 60 tons with tender full, can haul up ten empty flat cars at one trip, these weighing 6½ to 7 tons apiece.

The great expense of operating this direct connection between Salt Lake City and Park City, is compensated for by the fact that its only competing line, the Union Pacific, runs by way of Ogden and requires about three times the distance for the same connection.

The Alta branch of the Rio Grande Western Ry., running from Bingham Junction to Wasatch, Utah, has about one mile of 5% grade.

This road is about 8 miles long, and is operated only during the summer season, though it is not troubled with snow.

* * *

THE BRITISH BATTLESHIP "HANNIBAL," recently launched, is said to be the heaviest warship ever built. It is 390 ft. long, between perpendiculars, 75½ ft. beam, and 10,180 tons displacement. A double bottom extends for 220 ft. in the central part, and terminates in a protective deck, which forms an arch across the ship, and covers the engine and boiler rooms and magazines. For 216 ft. of the length are armor belts, 14¾-in. wide and 9 ins. thick; where the side belts terminate, bulkheads 12 to 14 ins. thick extend across the ship, and the belts inclose the citadel. The main battery will include four 12-in. and twelve 6-in. breech-loading rifles.

SCIENCE AND ENGINEERING.*

Thomas Curtis Clarke.**

The subject of this address is "Science and Engineering," showing the necessary relations between them, which are becoming closer and closer every day, as engineering extends over wider and wider fields of action. Science is the discovery and classification of the laws of nature. Engineering, in its broadest sense, is the practical application of such discovered laws.

The education of the engineer is now becoming as broad as that of any of the other professions. Engineering has become a profession, but it is the latest of the professions.

Herbert Spencer has shown that our present professions, law, medicine, architecture and engineering, have all developed from the clerical profession. A profession requires special education and instruction on the part of its professors, and in early times there was but one educated class—the clergy—and they were the only ones who knew enough to be lawyers, doctors, architects and engineers.

An art requiring so much technical skill as architecture was originally practiced by the clergy, as temples, churches and monumental structures naturally fell under their supervision. The great cathedrals of the middle ages were built by the higher clergy of those days, among whom William of Wykeham and Abbot Suger are deservedly famous.

The earliest engineers of whom we have any record were the priests of Egypt, whose wonderful works in masonry are surpassed by no masonry works of our days; and the only way in which we can show our superiority is by our greater skill in the use of metals. Civil engineering did not become separated from the clerical* profession until in much later times. The Latin word "pontifex" means a bridge builder and also a priest, and from it the words "pontiff" and "pontifical" are derived. The building of a bridge was considered such a remarkable feat that the name pontifex became the highest clerical title.

Men of inventive talent, not clergymen, displayed much skill in inventing and operating engines of war, hence the name engineer. Civil engineer was a later title, and thus indicates a later development. Civil engineering is the youngest of the professions, and the reason of its late evolution is that if engineering be the application of nature's laws, there could be no engineering profession until these laws were discovered. These discoveries did not come until late in the world's history, and the progress of science was much retarded by the conservative spirit. The works of Copernicus were suppressed. Galileo was imprisoned and Bruno was burned. Even Newton's splendid discovery of the laws of gravitation was not accepted.

Equally wonderful with some of the later discoveries of pure science are the discoveries in those branches of science which can be applied to the use of man, and in whose application the engineer takes no mean part. We have now the new chemistry, which is synthetic as well as analytic. In other words, it not only investigates the composition of bodies, but has learned how to create them by its own processes. It has revolutionized nearly every art and manufacture.

Another important very late discovery in medico-biological science is that of the presence of microbes, which exercise such a great influence upon human life and health. Here the labors of the engineer have come into play and have shown us how to purify water and sewage.

By far the most striking application of science in this century has been in electricity. Morse and Henry have given us the telegraph; Bell, the telephone; Edison, the incandescent lamp; Tesla, the alternating current, and McFarlan Moore hopes soon to give us artificial daylight from glass tubes, in which are no loops nor carbons, but only repeated interruptions of an electric current in a high vacuum. It has also given us the separation of metals from their solutions, and the economic transmission of energy, which has re-created our street railways, machine shops and manufactories, and may soon supersede steam locomotives, where frequent stops are necessary.

Its new discoveries come so fast that one can hardly write them down. Even while preparing this address a great discovery is announced. It has been the dream of investigators to find some means of producing electrical energy from coal without combustion. We now hear of a very simple process by which over 80% of the potential energy of carbon can be converted into electrical energy by causing the oxygen of the air to combine with carbonaceous material, through an intervening electrolyte, preferably melted caustic soda, according to Prof. Cross, of the Massachusetts Institute of Technology.* Assuming that this is true, we may say positively that this discovery will not be of value until the engineer has put into it such practical shape that it will be commercially successful. It may take the place of chemical batteries, but that it can supersede the steam boiler, where great power has to be produced, seems doubtful.

The discovery of the X-rays is but in its infancy. It can show our bones, but has not been able to penetrate a steel eye-bar and show the bridge engineer any hidden defects. It seems probable that its application to incandescent lighting is near at hand. The engineers are working at this problem.

By military engineers the laws of Nature are applied for the defence of mankind, and experience in the last great wars has shown that that nation which has made the greatest advances in engineering is the most formidable in war. It has been well pointed out by the President of the British Institution of Civil Engineers that all improvements in modern instruments of both attack and defence are the work of engineers.

Before the close of this century we may see another new branch of engineering. Through the labors of engineers man may soon extend his dominion over the air, and aviation engineers may be as numerous as mining engineers now are.

All the great discoveries of science have been made by the application of what is called the scientific method of investigation. This is as necessary to the engineer as it is to the investigator of pure science. Unless he is equipped with it and understands its use he will always occupy a subordinate rank instead of taking his true place as a master of creative science, which I shall show that engineering really is.

Scientific method consists of observation, deduction and experiment. We must not be deceived into thinking that one thing has no connection with another, because we do not see that connection. We must not draw hasty conclusions, but sift the facts after collecting them, rejecting those that have no bearing, and taking great care not to overlook or reject those that are of importance.

---

*Abstract of the address delivered June 30, 1896, at the annual convention of the American Society of Civil Engineers, held at San Francisco, Cal.

**President, American Society of Civil Engineers.

*Sodium hydrate is melted in an iron pot and a carbon cylinder is immersed in the molten material. Air in fine jets is blown through the hydrate. The oxygen from the electrolyte combines with the carbon and an electrical current results from the direct oxydation of the carbon, without any material accompanying generation of heat. The supply of air constantly regenerates the hydrate by supplying fresh oxygen to replace that which has entered into combustion with the carbon.

In forming a theory to account for the phenomenon, one must be very patient and get all the facts first, and not form the theory first and then try and find facts to fit it. This is the pit which scientific men too often dig for themselves and fall into. The first step, after forming the theory, is to test its truth by renewed observation and by careful experiment, which Huxley calls an artificial observation of facts. The art of experimenting is not to be learned in a day, but should form the apprenticeship of the engineer.

When a man, having formed a plausible theory, and having found it corroborated by experiment, suddenly runs against some obstinate beast of a fact that upsets it altogether, what shall he do? Shall he abandon the theory, ignore the fact, or go on patiently looking for newer facts? This is the test which shows whether he is imbued with the true scientific method or not.

True science begins with the use of mathematics and the invention of instruments of precision. Astronomy began to be a science with the invention of the telescope, and engineering with the invention of some kind of leveling instrument.

Fortunately we have now an abundance of technical schools, in which those intending to be engineers can be trained both mentally and physically in the very things that they ought to know. They can be trained in mathematics and the physical sciences; while in chemical, physical and electrical laboratories they can be taught the essential arts of experimenting. They learn the use of delicate instruments, and the art of drawing. Already has our profession felt the great influx of young men, trained and cultured in all these things.

Looking at the great numbers of young men who are yearly graduating from the technical schools and entering the ranks of our profession, the fear has sometimes been expressed lest there may not be room for all.

Engineering, following the general law of evolution, has become, and is still becoming, specialized, and specializations come constantly to meet new wants. Thus, we now see developing a special class of engineers created by the great value of land in cities, calling for very high buildings, and requiring experts to design their metallic frames and their foundations, made complex by their limited spaces, and the necessity of avoiding encroachment on others.

Some persons confuse civil engineering with structural engineering. We read in the prospectus of one of our technical schools that courses are given in mechanical, mining, electrical and civil engineering. What is meant is structural engineering, or the art of constructing earthworks, piers, walls, dams, bridges, roofs, viaducts, etc. The term civil engineering has a much broader meaning, and comprehends all engineering except military and naval. It includes all useful works of sufficient magnitude and intricacy to require scientific method, knowledge and skill in their construction. The civil engineer's true position is similar to that of the architect, who commands the services of many different professions and handicrafts. Mechanical and electrical engineers and many others aid him in their several lines, but from him comes the comprehensive design, and he alone is the director-general of the works. Such is the position claimed for civil engineers in Britain and on the continent of Europe. The members of our society should claim it here, and not only claim it, but show that they are capable of filling it. There is but one way in which they can do this, and that is by showing themselves masters of scientific method and knowledge.

The war between theory and practice has nearly come to an end. We now recognize that either without the other is not of much value. The practical man is one who has had experience in his own special line, and within his narrow limits he is not likely to make mistakes. The theoretical man without experience is a dangerous guide. Hence we wisely treat the young man, trained only in the schools, as an apprentice, and make him follow instructions until he gets experience. When he has got it, he rises very fast, and soon becomes a master, and in the race of life passes the "rule of thumb" man.

The progress of civil engineers in the future will be far greater than it has been in the past. Civil engineers will take a much higher rank in public estimation than they have done, and greater emoluments will follow.

When science (the accurate knowledge of what others have done) and experience (the knowledge of what we ourselves have done) are united in the same person, then we may truly say that we have seen the evolution of engineering from a craft to a profession.

◆

A MUNICIPAL ELECTRIC LIGHTING PLANT is again under discussion at Milwaukee, and it is proposed to have Mr. Geo. H. Benzenberg, M. Am. Soc. C. E. City Engineer, still further investigate the subject. A year ago, it is said, he went into the subject quite exhaustively.

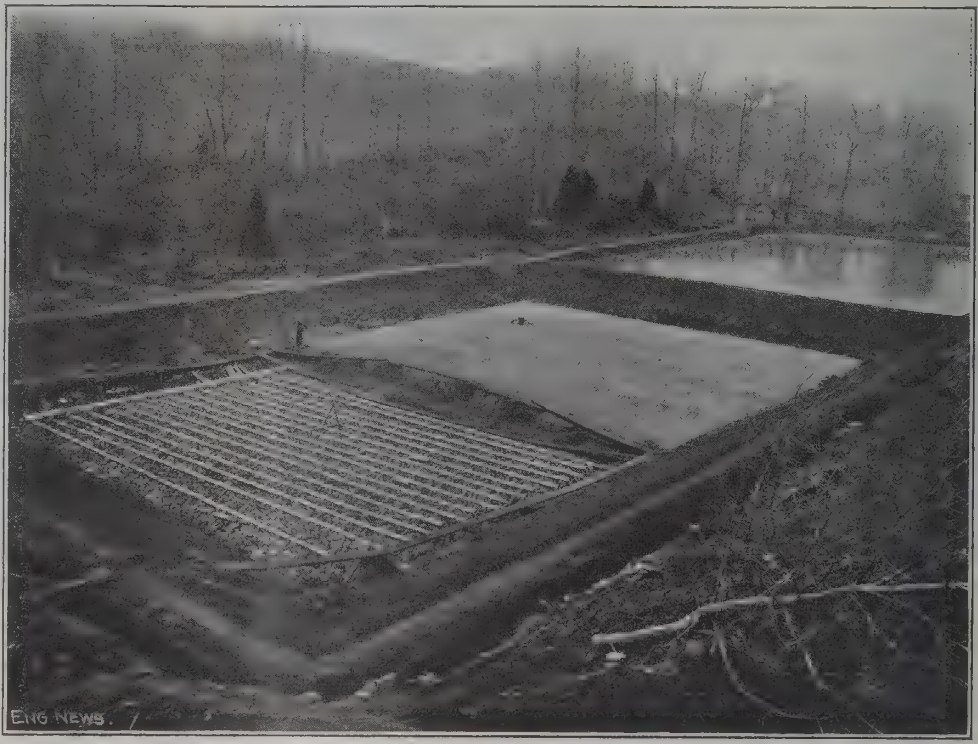
◆

WEIR GAGINGS OF THE GENESSEE RIVER at the site of the proposed storage dam, near Mount Morris, N. Y., are reported as to be made by Mr. Geo. W. Rafter, M. Am. Soc. C. E., of Rochester.

SAND FILTER BEDS FOR THE WATER-WORKS OF LAMBERTVILLE, N. J.

By Churchill Hungerford.

The water supply of Lambertville is impounded in two reservoirs made by building dams across a small stream at points about 2,000 ft. apart. The reservoirs are very shallow. The bottom consists of a light, clayey soil, which makes the water very muddy when agitated by wind or currents. In addition to this, large numbers of carp, which infest the reservoir, probably increase the turbidity. The clay in suspension is so finely divided that a week's sedimentation has very little effect upon it. As there is very little inflow to the reservoirs during the months of July, August and September, the water becomes stagnant and highly charged with organic matter, giving rise to a very strong "fishy" taste and odor. It was with the intention of removing these objectionable features that the filter beds were constructed.



THE FILTER BEDS AT LAMBERTVILLE, N. J., DURING CONSTRUCTION.

The beds are situated on a small plateau immediately below the lower or distributing reservoir and occupy two rectangular basins, each of which is 130 ft. long, 92 ft. wide and 9 ft. deep. As there was 10 ft. difference in the elevation of the opposite corners of the plateau, the basins were so arranged that the excavation necessary to form one supplied the material to make the embankment for the other.

A puddle trench, 4 ft. wide, excavated to the underlying rock runs through the middle of all embankments. This varies in depth from 4 to 16 ft. A single row of 2-in. hemlock sheet-piling was set to prevent crawfish from penetrating the banks. After the basins were finished, a layer of sand, 1 in. thick, was placed on the natural clay bottom. Paving with rough stone followed this, and sand was sifted into the interstices, thus insuring the filtered water against coming in contact with the clay. This pavement formed a foundation for the underdraining system which consists of:

(1) A 12-in. conduit, running the entire length of each basin, composed of vitrified pipe with a 4-in. tee every 2 ft. This conduit connects with a 12-in. cast-iron pipe leading to the receiving chamber, where it terminates in a gate or valve. The 12-in. joints in the vitrified pipe are calked with jute.

(2) A series of lines of 4-in. vitrified pipe, running at right angles from the main conduit to the opposite side of the basin. These lines are 2 ft. apart, plugged at the end and laid with open joints. They are not laid level, the ends opposite the conduit being slightly higher. The intervening space between the lines was filled with riprap to the top of the pipes. Gravel would have done equally as well, but as all sand and gravel had to be hauled three miles, besides paying 32 cts. toll for each two-horse load, it was found more expedient to use random stone.

Two layers of gravel, the lower layer coarse and the upper fine, were placed over the pipe. They had the same rate of grade as the pipe; the gravel was washed before placing. The only sand that could be obtained contained a large amount of loam, and had to be thoroughly washed before being used. Great care was exercised during this operation, as it was found that too much washing was worse than too little, on account of the finer particles being carried away with the loam, leaving the residue too coarse. Besides containing loam, the sand was not sharp, and about 20% of it consisted of rounded nodules of slate, which could not be removed by washing. The sand was found to contain 33% of voids.

The filter beds proper, or sand layers, average 2½ ft. in thickness, being thickest at the corner nearest to the receiving well, each bed measuring 60 × 100 ft. on the surface. The sand was placed while wet, so that there would be less settlement when covered with water. To insure a perfect contact with the banks, sand was beaten into the slopes as high as the surface of the sand bed.

The slopes were riprapped to within 1½ ft. of the top of the embankment, to prevent the unfiltered water, which stands on the surface of the sand to a depth of 3 ft., from washing the slopes. The flow line in the filter is 10 ft. lower than that in the reservoir, but two butterfly valves, operated by floats, regulate the inflow. These floats are in the receiving chamber, and are operated by the filtered water. As the sediment layer on the surface of the beds increases in thickness, the flow of water through them is retarded, and the level of the filtered water in the chamber is slightly lowered, thus opening the butterfly valves and causing the unfiltered water to rise until the head has increased sufficiently to close the valves. This process continues until the water over the sand is 4½ ft. deep, when it passes out of the overflow. It then becomes necessary to clean the filters. A waste pipe was provided for each basin, so that their contents could be drawn off at any time.

The filter was put in operation on May 4, 1896, at which time the average daily consumption was only 225,000 gallons. Water was allowed to enter the basin at a slow rate until it was 1 ft. deep over the sand, when it was turned on at full head. A peculiar feature noticed in the sand was its instability. A workman having occasion to go on the bed when there was about 3 ins. of water over it, sunk down through the sand to the gravel beneath. It immediately settled around him and he had great difficulty in withdrawing his legs. The bed was a veritable quicksand.

On the following day the water was drawn off and an examination made. A few saucer-shaped depressions about 3 ins. deep and 12 ins. in diameter, appeared on the surface of the sand. On investigation, these were found to have been caused by the displacement of the lower layer of gravel, which allowed the material above to fall into the voids in the riprap. As it was found no sand had entered the pipes, the depressions were simply filled with sand and no further trouble was experienced from this source.

On May 10, after five days operation, the water was again lowered. Although the unfiltered water was slightly turbid, there was no indication of a sediment-layer on the surface of the sand. On the contrary, it was covered with the nodules of slate before mentioned. Some of these were 1-10-in. on their longest diameter and oscillated with the slightest motion of the water. The basins were again filled, and two days later, May 15, a marked change being noticed in the effluent, an analysis was made which showed a marked improvement. On the day following, the surface of the sand was examined and found to be evenly covered with a thin sediment layer. The bed was compact and hard.

On May 19 the flow line had risen about 3 ins. above the 3-ft. level, but on the day following it dropped back to the normal level. As the effluent was good, the filter was allowed to run until May 26, when the trouble was located in the basin next to the dam. After the water was drawn off, an examination showed that at a point where a ledge had been blown out, water had penetrated the seams in the rock above the sand and then found its way into the gravel layer beneath, thus contaminating the filtered water. A plating of clay on the slope where the rock was taken out remedied this defect and no further trouble was experienced with the working of the filter.

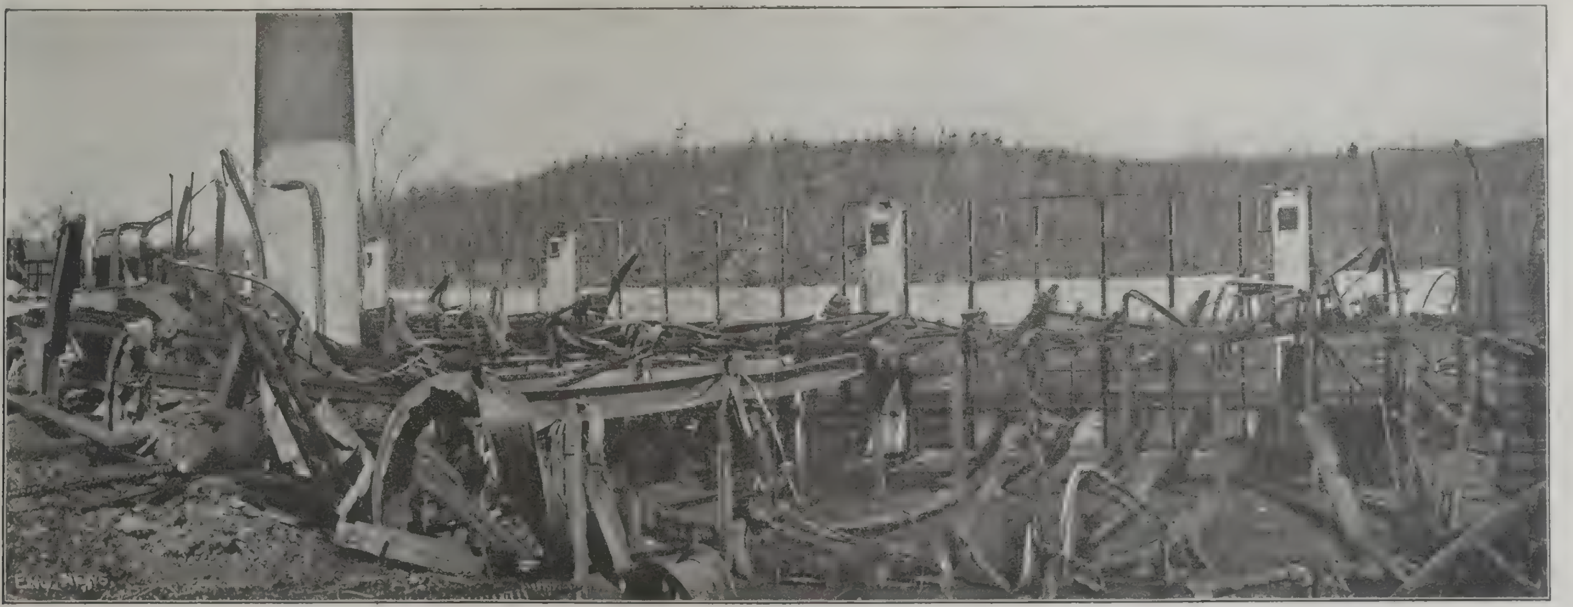
The beds were cleaned on May 28, at a cost of $6, or 50 cts. per 1,000 sq. ft. At this rate, the cost of filtration, not including interest on plant, is $1 per 1,000,000 gallons.

An experiment was made to determine how nearly the friction in the underdrains had been compensated for by varying the thickness of the sand layer. (As before stated, this layer was thickest at the corner nearest the receiving chamber and thinnest at the corner diagonally opposite.) Water was let into the filter until it was even with the surface of the sand and two holes, about 3 ins. deep, were made at the points where the sand was thickest and thinnest, respectively. Water was then drawn from the filter at the rate of 3,000,000 gallons per diem per acre. As soon as it disappeared from the surface of the sand, the elevation of the water in the two holes was taken and found to be 0.11 ft. lower at the point near the receiving chamber. This difference in elevation is probably due to the fact that the friction of the water on entering the joints is greater than estimated, consequently, that portion of the bed nearest to the outtake is performing higher duty than the more remote portions. While, in moderate sized filters, this difference in the rate of filtration of the various parts of the bed is undoubtedly regulated by the sediment layer, it is extremely doubtful if the best results can be obtained from filters of considerable area, having pipe underdrains, without compensating in some manner for the friction in the underdrains.

The plant was constructed for the Lambertville Water Co., from plans made by the writer, at a cost of $5,600.

THE RESULT OF A FIRE IN A STEEL-FRAME FACTORY BUILDING.

The accompanying view is an excellent example of the way in which unprotected iron structural work fails when subjected to fire. The building was the wire factory of the Quinsigamond Works of the Washburn & Moen Mfg. Co., at Worcester, Mass., and the fire occurred about 9 a. m., on Sunday, April 5. The following particulars are taken from the April circular of the Boston Manufacturers' Mutual Fire Insurance Co., and for the photograph from which our illustration is taken we are indebted to Mr. John R. Freeman, M. Am. Soc. C. E., of Providence, R. I., and Mr. T. J. Porden, President of the State Mutual Fire Insurance Co., of Providence, R. I. The view shows the complete twisting and distortion of the ironwork. The loss involved was $151,130.



EFFECT OF A FIRE IN THE SPRING FACTORY OF THE WASHBURN & MOEN MFG. CO. AT WORCESTER, MASS., APRIL 5, 1896.

The building was two stories in height, with a basement under one end, and had a steel frame supporting the floors and roof. The posts were built up of steel shapes; the floor beams were built-up I beams spaced about 8 ft. c. to c. The second floor was of plank covered by a hardwood top floor. The roof beams were 6 × 12-in. timbers covered with the ordinary plank and gravel roof, the whole supported by the built-up steel columns. The walls were of brick up to the window sills, the remaining part being mostly glass. The window frames were of steel, so that all the woodwork there was in the building was the plank and timbers in the roof, the plank in the second floor, and also the plank over a portion of the first floor, the remaining part of the first floor being of brick. At the end where the fire started the floor was of brick.

The basement at the south end was occupied by the boiler and engine rooms. The first story was occupied by the japanning room, which was separated by a brick wall from the remaining part of the building, and by the hardening and annealing furnaces, the floor at the end of the building occupied by the furnaces being of brick; and the second story was occupied by the special machines for shaping the springs. The floor of this building was free from oil, but the brickwork in the floor below was saturated.

Oil was used as a fuel at the tempering and hardening furnaces in this building, this oil being stored in two large tanks located outside of and near the lower end of the main building. From these tanks the oil was pumped to a secondary tank located on a trestle work near the upper end of the building, from which it flowed by gravity through a 2½-in. pipe to the burners, the pipes being arranged in such a way that when the pumps stopped, the oil in the secondary tank flowed back to the storage tanks, and it was supposed that the oil remaining in the feed pipe would flow to the burners and there be burned up. Located in this feed pipe was a so-called trap, consisting of eight or ten feet of 3-in. or 4-in. pipe. This trap was provided to catch the first delivery of the oil when the machine was started up, this first flow of oil not being of the right consistency to properly feed the burners.

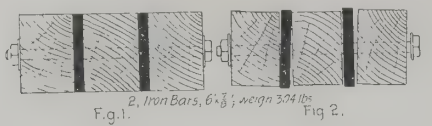
The repair hands were at work making some changes in this feed pipe, and when they disconnected it a small quantity of oil in the pipe immediately flowed out and down onto the portion of the ovens located near the burners. These ovens had not been operated since the afternoon of the day before, but were still hot enough to vaporize this oil and set it on fire. The flames immediately spread throughout the building and almost entirely destroyed it. When the flames reached the upper story the columns supporting the roof immediately collapsed, being bent and twisted. According to the story of eye-witnesses the roof immediately fell, thus adding a large amount of material to the flames.

Nearly the entire building was destroyed. The boiler and engine room in the basement was, however, nearly intact, due to its being fully protected by automatic sprinklers.

It was at first thought that the fire spread over the brick floor in the first story, but it appeared later that fire was communicated from one end of the building to the other upon a condensed and somewhat gummy deposit on the bottom and sides of the I-beams as well as upon the bottom of the planks upon the second floor, generated from the dipping of the heated springs into fish oil for tempering. This thin film of oily deposit on the ceiling and beams of the first floor, and the opportunity on every square inch of that floor to ignite the plank, would sufficiently account for the rapid spread of the fire. The most singular point disclosed in this study of gaseous fires was the very small quantity of oil or of oily or of loose and fibrous stock which will generate a great volume of gas. The adhesive gum said to have been deposited on the ceilings and beams from the effect of the immersion of heated steel in oil would correspond to a coat of shellac varnish, the danger of which is well established. Fortunately the combination of conditions is very uncommon.

The ends of the building, in contemplation of extensions, were of boards fastened to the steel frame. One end was destroyed, the other was impaired but not consumed.

The work done in this building was making steel springs, and there was no wood of any consequence in the building except the material of the floors, roof and ends as above described. There was no fire in or about the building at the time when it was ignited and destroyed. The steel springs, for the manufacture of which the building was devoted, were tempered in the basement in fish oil and the bricks had apparently become saturated with this oil. The operations in the works had ceased, and the pits in which a part of the work of heating is done had been free from heat for a period of time estimated at 16½ hours before this fire occurred. In undertaking the repairs of the oil pipe, the work was done in such a way that a very small quantity of crude petroleum contained in the sag of the pipe went into the works. It there ignited from the heat retained after the regular work had ceased for over 16 hours, undoubtedly generating combustible gases, which, passing along the floor and along the ceiling, may have generated additional gas from the fish oil which had been absorbed by the brick, or possibly from deposits upon the ceiling derived from the constant heating of oil with heated steel. The heat and gas passing upward created the very uncommon condition of very rapid gaseous fire to which previous reference has often been made, and to which infrequent cause in at least three cases very heavy losses have been attributed, one being the heaviest ever incurred by the company. It is noticeable that the excessive heat by which the frame was distorted must have been mainly in the two upper stories. This was proved by finding some parcels of paper and some varnished wooden boxes on the main floor above that part of the basement where the sprinklers worked which were unimpaired after the extinction of the fire.



Figs. 1 and 2.—Flitch-Plate Bolster for Freight Car Before and After Shrinkage.

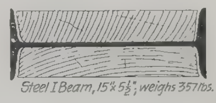


Fig. 4.—A Poor Design for Combination Wood and Iron Bolster.

This building was not protected throughout by automatic sprinklers. Whether automatic sprinklers could have stopped such a gaseous fire in the upper stories is an open question on which the several experts who have examined the case since the fire were at variance. The only rule under which sprinklers could have been called for in such a building would have been the absolute rule often advised but not yet insisted upon as a condition of taking insurance on such buildings as this, except in the place where they were put in; namely, to put sprinklers everywhere, especially in the works or departments of works where fire or loss seems least likely to occur. The general conclusion is that sprinklers would have so cooled the air as to have prevented the distortion of the steel frame.

The question arises in this case on the relative merits of heavy timber as against unprotected steel, and it is apparent that the destruction of this building with its contents may be almost wholly attributed to the heat developed from the oil, rather than from the combustion of the wood of the floors and roof, which was the incident in the course of the destruction, rather than the cause. This will be apparent from the fact that the floor over the first story was left much less impaired by fire than the floors above, where the principal effect of the heat developed by the rising gas was most fully destructive upon the steel frame. The wooden beams which constituted the support of the roof were impaired to the depth of only about 1 in., and would have sustained the roof except for the giving way of the metallic framework underneath. There is little doubt in the minds of all the experts who have examined the conditions of this loss that a heavy timber frame would have resisted the conditions of this fire until it could have been extinguished with moderate loss, the pumps at the other works having been started in time.

A CENTRAL AMERICAN EXHIBITION is to be held in Guatemala in 1897, and manufacturers and others of the United States have been invited to exhibit.

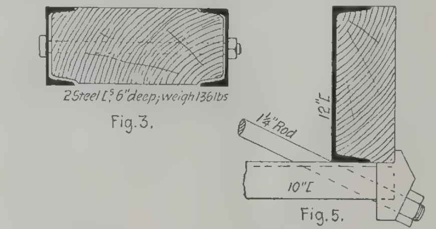
METAL UNDERFRAMING FOR FREIGHT CARS.*

(With inset.)

With the gradual and steady increase in the carrying capacity of freight cars and in the hauling power of freight locomotives, the insufficiency of the earlier methods of freight car construction, developed from wagon building, consisting of timber framing held together by nails, spikes, straps, lag-screws and bolts, became more and more apparent.

The lessons learned on the repair tracks led to the strengthening of freight car body bolsters and longitudinal sills with truss rods, and, finding this to be still insufficient, the timbers have been reinforced with iron and steel as in the well-known flitch-plate bolster, Figs. 1 and 2, or in the fairly effective plating of bolsters, end and longitudinal sills as at Figs. 3 and 5, where the metal is disposed to the best advantage and the shrinkage of the timber can be readily followed up, or as at Fig. 4, where the metal is disposed in its weakest position to withstand the main load that a bolster has to carry.

Some designers, recognizing the inherent weakness in any composite form of construction where wood is used, went at once to iron for body bolsters, and the iron body bolster of which Fig. 6 shows two general types was the result, although in its earlier forms it was made too flimsy and was not sufficiently braced to withstand the bending strains, side-bearing pressures, etc. A more recent form of iron bolster is shown in Fig. 7. A simple, very strong and cheap steel bolster, which has stood the test of service well, is shown at Figs. 8 and 9. Here should also be mentioned the Schoen pressed steel, American and Shickle, Harrison & Howard cast-steel body bolsters, which have been extensively illustrated in the technical journals and are well known to the members.



Figs 3 and 5.—Method of Strengthening Wooden Bolsters and Side Sills. Lehigh Valley R. R.

Figs. 22, 23 and 24 mark a long step ahead in that the center sills, as well as the bolsters, are of steel. It is very probable that the use of iron and steel in car construction would have advanced far beyond its present standpoint but for prejudice which has grown up in the minds of many against any and all iron or steel cars, as the result of some unfortunate ventures in which the designers either did not fully understand the service and strains a freight car has to withstand, or from lack of experience; and in an endeavor to keep the weight and cost of their cars down to limits which would enable them to make sales, placed cars in service that have become a by-word on account of their frequent and prolonged sojourns on the repair tracks.

It would be quite as unjust to condemn all iron or steel car construction on account of these failures as it would be to condemn the use of wood in car construction because some of the earlier builds of cars, and even some comparatively recent designs, are so poorly proportioned that they are constantly failing. The obviously proper course is to profit by these early failures in iron car construction, make use of the experience gained and go on with the development of the steel car frame, trying to avoid the errors of the past. It is only necessary to remind those present of some of the exhibits at the Chicago Exposition to show that progress has been made in the right direction.

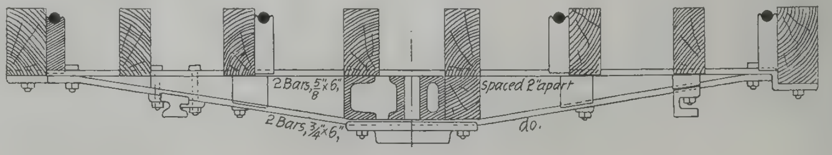


FIG. 6.-TWO EARLY DESIGNS FOR IRON BODY BOLSTERS.

It would be eminently desirable if the M. C. B. standards could be issued in advance for the guidance of railway companies instead of being adopted after the need for such standards has led to the use of a multiplicity of designs, which add to the expense and delay in car repairs. Car building is anything but an exact science, and the evolution of a standard design for an iron or steel car frame must come after many experiments, errors and failures, profiting by which experience we will ultimately achieve success.

Even if the members of your committee felt that they could present a design for standard steel framing for freight cars which would be practically perfect and require no future modification (which is not the case), it would not be practicable to do so until greater uniformity in the lengths and sizes of interchange freight cars for given capacities has been brought about. It is hoped that a thorough inquiry into the subject will be made by the association by means of a committee to recommend standard lengths of sills and widths over sills for refrigerator, box, stock, flat, drop-bottom and drop-end gondola cars of 60,000, 70,000 and 80,000 lbs. capacity, and that the association will adopt such standards.

After this step has been taken, then with sufficient experience and knowledge to guide them a committee could take up the subject of steel underframing for freight cars, and with good hope of success present to the association a series of designs for M. C. B. steel underframes that could be adopted and used, as far as their general features are concerned, without fear of serious failure ensuing.

As long as the main framing of foreign freight cars coming on our repair tracks is of timber (which can be cut and dressed to suit by the ordinary carpenters' tools), and of iron truss rods and bolts (which can be cut or welded by any blacksmith), odd sizes of sills, etc., are not such a serious matter, but when we come to steel and iron, which require heavy machine tools and shop treatment, and where odd sizes or shapes must be specially ordered and rolled or forged at the forges or mills, the question of uniformity of sizes becomes one of paramount importance.

With standard lengths, depth, width of flange and weight per foot for sills of all flat-bottom cars of 60,000, 70,000 and 80,000 lbs. capacity, the rolling mills can carry the stock ready for instant shipment, feeling safe that they will not have it left on their hands as obsolete stock; the sills and shapes in stock at any railroad shop store would be certain to suit any foreign car that might come on the repair tracks, only requiring that the holes, etc., should be laid off and punched or drilled to suit the details of the particular car, but before this happy state of things can be brought about, the standards for lengths and widths of cars must be adopted, and, when steel-framed cars are built, rigidly adhered to.

Pending the adoption by the association of the standard lengths and widths for given capacities, your committee present the following rules or recommendations, which they feel justified in asserting should be seriously considered by designers of steel framing for freight cars:

1. Specially forged, pressed or rolled shapes, cast steel, etc., or patented forms of construction are undesirable for cars to be used in general interchange business, no matter how well designed theoretically, for the reason that when such parts are damaged there must necessarily be long delays in ordering and obtaining these special parts, and should the parties who have furnished them go out of business, or change their molds or patterns, the parts cannot be duplicated for repairs except at enormous expense and loss of time.

2. Steel and iron bars and shapes of standard bridge specifications and regular market sizes should be generally preferred, so that railroads and car builders can avail themselves of the competition in the open market when purchasing, or if not equipped to put steel frames together themselves, can have this work done for them at any of the numerous bridge-building concerns on competitive bids, the underframes, riveted or bolted together, can be shipped by carload lots to the car shops to be completed into finished cars.

3. Get-at-ableness in the design is of the greatest importance in keeping down the first cost and maintenance; parts that are to be riveted together should be so arranged that they will be equally convenient for hydraulic or power riveting when the car is being built, or for field riveting in repair work.

4. In designing riveted work, it should be laid off with plenty of rivets, these to be spaced close, as in boiler work, and the same care to insure true fair holes, hot rivets, well driven and completely filling the holes as in first-class boiler work, is necessary. Complaints sometimes heard against riveted work in car frames and tender frames, on account of loose rivets, can be directly traced to an insufficient number of rivets and poor riveting.

5. If bolts are used to hold iron or steel parts in position, not merely to carry weight, they must be turned bolts (a driving fit), in carefully reamed holes, fitted with the greatest care. When so fitted they will probably give no trouble from working loose, but as this is machine shop work, such bolts should be avoided as far as possible, as it is not likely that such bolts will be fitted in this way on the repair tracks, while it is reasonable to expect that a hot rivet, well driven, can be put in anywhere with the aid of a portable forge. In both riveted and bolted work it is of the utmost importance to per-

R CONSTRUCTION.

Freight Cars," Master Car Builders' Association.)

CHAS. HART & SONS, LITH., 36 VESEY ST., N. Y.

fectly fill the holes, remembering that it is the "initial wiggle," if only 1-1,000 part of an inch, that will surely produce loose rivets and bolts and oblong holes; no amount of hammering on the heads of rivets, or tightening up nuts or bolts, or the use of lock-nuts, nut-locks or fibrous washers will be of any use if the holes are not perfectly filled.

6. Every structure has a foundation, every machine has a bed-plate, every animal, bird, fish, and most of the higher works of nature, have a backbone or spine on or around which the structure is framed; this cardinal principal of design seems to have been largely overlooked in freight car construction, and it is believed that the center sills of a freight car should be made its main strength and reliance, and that the entire load shall be carried from the platform, the upper works being simply arranged as a housing to confine and protect the load.

7. To enable the center sills to withstand collision and severe shocks to the best advantage, these sills should be placed so that they will be directly in line with the dead blocks, and thus take the buffing and collision shocks in direct compression. Also there depth should be such that at least the center line of draft and centers of the dead blocks will be within the vertical dimensions of the sills. When so arranged there will be no tendency from shocks or pulling strains to bend the center sills, either laterally or vertically, or to bend or break the end sills.

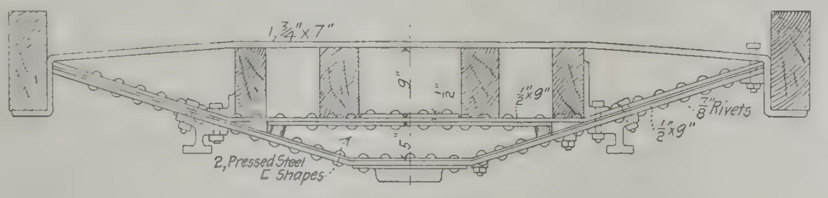

FIG. 7.—RIVETED PLATE BOLSTER FOR 70,000-LB. CARS. NORTHERN PACIFIC R. R.

8. That care should be taken to avoid punching or drilling holes in the flanges of channels or I-beams where these are subject to heavy strains, especially tension or bending strains, unless additional material is added to compensate for this.

9. That with the change from wood to steel, the necessity for truss rods no longer exists for cars of reasonable lengths, but that ample and sufficient strength can be obtained within reasonable limits of weight without the use of truss rods and consequent need of adjustment.

10. On account of the sweating and rusting of iron and steel, wood is preferable to iron or steel for flooring, siding and lining of merchandise and stock cars. Much has been said and written on the subject of corrosion of iron and steel break beams, bolts, pipes, rails, etc., from the action of sulphuric acid leachings from coal cars and salt-water drippings from refrigerator cars and manure drippings from stock cars. There is no doubt that there is serious corrosion from these, and other causes under certain conditions, but evidence exists that steel framing under tenders and iron work under coal cars in constant service, and steel framing of cars exposed to very damp and destructive climatic influences for many years, have not suffered materially from these causes. Doubtless preservative paints can be found that if properly used when the steel frames are first built and with occasional repaintings will sufficiently protect the steel from corrosion, but as this is a very important subject your committee would recommend that it be made a special subject for committee investigation by a series of tests ranging over nine or ten months' time.

There is an economical side to this question which your committee desires to call attention to before closing their report, namely, how much additional weight and how much additional first cost dare be put on a car without ultimate loss.

1. As regards the question of increased light weight of freight cars of given capacities having steel underframes, your committee feel that they need only state that it is proved to be quite practicable to build cars with steel frames of greater strength and capacity with less light weight than when wooden or composite underframing is used, and that with more experience in the right methods of construction and a proper appreciation of the capabilities and best uses of steel the proportion of carrying capacity to light weight can be still further increased for large capacity cars without danger of increasing the subsequent running repair account.

2. With regard to the question of probable increased first cost of freight cars having steel underframing, the burning question here is, "Will it pay?" There are so many factors governed by local conditions which must enter into the calculation, that each company must perforce figure this out for its own set of conditions.

One factor, namely, the repair account, should, however, here receive passing notice. From the best information obtainable your committee believes that it is very nearly correct in stating that the charge for wheels, axles, springs, paint, chain, brake-shoes, brasses, couplers, and other parts that will wear out and fail as much under the most perfect steel-framed car as under the poorest design of wooden-framed car in the same service will constitute about 50½% of the average total cost of freight car repairs, exclusive of inspection, oiling and packing. Then the two questions remain:

1. Of the remaining 49½%, how much can probably be saved by the use of a perfect steel underframing which would require no repairs except painting during the life of the car?

2. Will this saving, added to the increased freight earnings of the car and to the increased mileage earnings when away from home (due to a less number of days per annum spent on the repair track), pay the interest and depreciation on the extra first cost of the steel car?

Taking the figures given in "Poor's Manual," the freight earnings per revenue car for 1894 were about $1.38 per day, and the average mileage earnings of cars away from home are only about 15 cts. per day.

Where the freight car repair work is being kept up currently, the number of cars on the repair tracks can be kept down to 4% of the total equipment; this means that each freight car would spend about 14½ days on the repair tracks each year. If we assume that only 40% of this could be avoided by the use of perfect steel framing, we can possibly save about six days on the repair tracks per annum.

This would mean, if the freights were available, increased freight earnings of $8.28 per annum per car, or 90 cts. additional mileage earned per annum per car away from home.

It is about right to assume, including private cars, that 30% of all freight cars are constantly away from home.

Taking one lot of 1,000 cars we can assume that as above the freight earnings could be increased.............	$8,280	per annum
The mileage earned from foreign roads increased..........	300	" "
	$8,580	" "
Estimated possible saving in repairs, say 20% of $72 per car per annum..	14,400	" "
	$22,980	" "

As the steel framing when put up in lots by bridge builders ought not to increase the cost of cars more than $75 per car at most, this figure of $22,980 per thousand cars for savings and increased earnings would approximate 36% per annum on the extra capital invested, amply sufficient to cover the depreciation and interest charges under the conditions above assumed.

In conclusion your committee begs to present the accompanying drawings of designs for metal underframing for freight cars for the consideration of the members, and begs that members will criticise these designs, using the ten rules or recommendations previously given as the basis for such criticism.

FIGS. 8 AND 9.—ELEVATION AND SECTION OF BOLSTER MADE OF I-BEAMS FOR CARS OF 60,000 LBS. CAPACITY. NORFOLK & WESTERN R. R.

R. P. C. Sanderson, Chairman,
J. D. McIlwain,
J. R. Skinner,
John Player,
Roanoke, Va., May 10, 1896. Committee.

THE NICARAGUA CANAL REPORT to the House of Representatives by the Committee on Interstate and Foreign Commerce, states that the committee believes the canal entirely feasible and strongly recommends that the government assist in the completion of the work even if it costs more than $150,000,000. The difference of opinion between the engineers for the government and for the company is thought to affect in no wise the practicability of the project. The committee believes that the main question now is, who shall build the canal and who shall control it when built. The committee feels justified in recommending that Congress should take immediate action to give such aid to the enterprise as may be necessary to obtain the funds which are requisite to complete the work.

GARBAGE AND ASHES must be kept in separate receptacles by New York householders after Aug. 1, in accordance with a regulation of the Health Department and an order issued to the various city departments by Mayor Strong. The new ruling is due to the fact that a contract has been made for the disposal of garbage by one of the utilization systems, as already noted in these columns.

AN AIR-CUSHION FOR ELEVATORS is provided for the safety of the elevators in the new Congressional Library Building at Washington, D. C. It comes into action in case a car should drop and the safety grips should fail to work. At the bottom of the elevator shaft is a well about 13 ft. deep, with the sides ⅛-in. from the car at the top and 1½-in. at the bottom, thus preventing a sudden shock. Satisfactory tests have been made with baskets of eggs in the elevator car and with the car carrying a load of 2,600 lbs.

A HOT-WATER MOTOR CAR for street railways is being tried experimentally at Van Cortlandt, N. Y., on a sidetrack of the New York Central R. R. The water is stored under high pressure in reservoir cylinders on the car, and flashes into steam as it escapes into the engine cylinders. The system is the invention of Mr. W. E. Prall.

THE MASSACHUSETTS PIPE LINE GAS CO. has been chartered by the Massachusetts legislature. The company has power to lay its mains practically anywhere it chooses, the location being subject to the approval of local governing bodies, or in case of non-approval a "reasonable location" is made by the State Board of Gas and Electric Light Commissioners. The company is not permitted to sell gas directly to consumers except through the purchase and operation of existing plants. The prices to be charged for gas are limited as follows: For fuel gas sold to other gas companies or to towns operating plants, per 1,000 cu. ft. of gas having an average heat value of 580 B. T. U., 20 cts. within five miles of the state house; 25 cts. between 5 and 15 miles; 30 cts. beyond 15 miles. For illuminating gas sold to gas companies or towns, the rates are limited to 5 cts. per 1,000 ft. in advance of the above prices, the candle power to be equal to that required by the state law. For both fuel and illuminating gas sold to individuals after the purchase of local plants, the prices must not exceed, within eight miles of the state house, 60 cts. per 1,000 cu. ft.; outside the above limit, in any city having over 75,000 inhabitants, 75, and in any other city, 90 cts.; in any town, $1.25 per 1,000 cu. ft.

THE CATARACT POWER & CONDUIT CO. has been incorporated with a capital stock of $2,000,000 to distribute current supplied from Niagara Falls by the Cataract Construction Co. The latter company will transfer to the new one the franchise granted it by the city of Buffalo. Among the directors of the new company are Messrs. Edw. D. Adams, President, and F. L. Stetson, First Vice-President of the Cataract Construction, D. O. Mills and John Jacob Astor, all of New York, and Geo. Urban, General Manager of the General Electric Co., of Buffalo.

AMERICAN MACHINERY FOR RUSSIA is to be supplied by several of the leading manufacturers of machine tools, as a result of the negotiations which are said to have been successfully carried out for the establishment of new locomotive works at Nijni-Novgorod by an American syndicate. Mr. E. D. Smith, of Philadelphia, and Mr. Walter F. Dixon, formerly with the Rogers Locomotive Works, are at the head of the concern.

RESPONSIBILITY FOR REPAIRS TO PHILADELPHIA street pavements are disclaimed by the street railway companies where the pavements are torn up by other corporations. The street railway companies are reported as saying that the contractors who put down the pavements for them, on streets where there are street car tracks, claim they are not required to make repairs under their guarantee where the pavements are torn up as above noted.

THE RAISING OF THE STEAMER "Ailsa" by means of barrels and caissons filled with air, is proposed by the Midland Salvage Co. The caissons are wooden cylinders 30 ft. long and 8 ft. diameter, with attachments for chains which are passed under the hull of the vessel. The chains are to be made tight with the caissons submerged, and the water then pumped out or expelled by compressed air. The "Ailsa" was sunk in the Narrows, New York harbor, on Feb. 29, by collision with the French Line steamer "La Bourgogne."

LONDON AGENCIES: KEGAN PAUL, TRENCH, TRUEBNER & Co. (Limited), Paternoster House, Charing Cross Road; SAMPSON LOW, MARSTON & Co., (Limited), St. Dunstan's House, Fetter Lane.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32*d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The statutory regulation of interlocking signals for railway grade crossings which was inaugurated in this country by the passage of a special law by the State of Illinois some nine years ago, has been slow to gather disciples, despite its very excellent results in that state, and it is with considerable gratification that we note on another page the recent adoption of a similar law by the State of Ohio. An examination of the Ohio law will show the following provisions: (1) By the installation of an interlocking plant satisfactory to and approved by the railway commissioners of the state, trains will not be required to stop before passing such a crossing. (2) When one of two or more railways crossing at grade desires to install interlocking signals, and the others object, that railway can by petition request the intervention of the railway commission, which, after due and proper hearing of all parties interested, may grant or deny the petition. If the petition is granted the objecting railways shall be compelled to co-operate in the installation of the interlocking plant within such time and at such a proportion of the expense as the commission may determine. (3) All future crossings constructed at grade shall be provided with interlocking plants at the expense of the railway desiring the crossing. (4) Any railway refusing or neglecting to obey the order of the commission for an interlocking plant shall pay a penalty of $500 per week for each week of delay.

The law applies to crossings of electric and steam railways as well as steam railways alone, being much more definite on this point than the older Illinois law. This is unquestionably as it should be, since the recent growth of electric railways has introduced an element of danger the importance of which was unsuspected a decade ago. It is only to be regretted in view of the many recent disasters from electric cars running into open drawbridges that definite provisions were not made by the law for signals in such cases, although the general intent of the law will probably be construed to cover such cases if the question should be brought up. Another provision of the law to be noted particularly is that it compels all steam and electric railways seeking to cross the tracks of any other steam or electric railway to protect the crossing by interlocking, and to pay all expenses of installation, maintenance and operation.

◆

Apropos of the recent discussion on "cheap engineers" in our column of "Letters to the Editor," a correspondent sends us a marked copy of a trade journal, containing on one page a letter from an "engineer," whom we will call J. Blank, and in a "Directory of Consulting Electrical Engineers," the professional card of the same man. We reprint an extract from the letter and the professional card in parallel columns as a luminous exhibit of combined innocence and assurance.

"I think the Steam Engine Indicator is the greatest instrument made from an economical standpoint, but until very recently I did not think much of it. Why? Because I never used one and did not know anything about it. Up to about two months ago, I was using far too much fuel; tried everything in the line of economy, but to no purpose; finally bought an indicator; put it on according to directions; first diagram shows a ratio of 124 to 60, or that one end was doing over twice as much work as the other, hence the belts would jump, engine would shake, dynamo would jar and spark. We equalize the engine; result, $27.35 saved in coal the first month, and we are still improving. The Indicator is a fixture in our plant."

J. Blank.

J. BLANK,
ENGINEER
AND
ELECTRICIAN.

Engines Indicated.
Power tests made.

Small Isolated Plants erected.
Plants overhauled and repaired on premises.
Repairing Arc Lamps a specialty.

◆

We have recently received two pamphlets entitled "Results of Tests made in the Engineering Laboratories of the Massachusetts Institute of Technology." They contain in tabular form the detailed results of many hundred tests of specimens of iron, steel, copper wire, timber, etc., besides records of trials of steam boilers, condensors, injectors and other apparatus. If the object of these pamphlets is to show that a vast amount of testing is being carried on in the laboratories of the Institute, they no doubt accomplish their object; but if the intention is to convey useful information to engineers, the pamphlets appear to be a failure. There is no index; the classification is imperfect; all tests of steel, for instance, to the number of about 240 are arranged in the order of the date of the test instead of being classified as to grade of steel, size of specimen, etc. The chief defect, however, is the lack of any summary of results or of any explanation whatever as to what the tests are intended to show and do show.

Perhaps it may be said that the tests were not intended to show any especial thing, but were merely the ordinary routine tests carried on to give the students training in the conduct of tests. But if this be the case, is it really worth while to spend the Institute funds to print these records in detail, merely on the chance that some information contained in them might be of value to some engineer?

On the other hand, it is stated in a very brief prefatory note that it is proposed to publish "such results of tests made as part of the regular work in the engineering laboratories of the Institute as may be of interest to the engineering public."

We gather from this that the professors who supervised these tests and selected them for publication, think that there is something in them more than mere routine work. Probably, too, they know what this "something" is. Then why not say, boldly and plainly, just what information of practical value is contained in this labyrinth of tables? In the absence of some guide of this sort, we greatly fear that the busy practising engineer will never attempt a search through this bewildering mass of figures merely on the chance of digging out some valuable piece of knowledge. Even the technical editor, whose special province it is to hunt up useful information in all sorts of likely and unlikely places, well nigh despairs at the task of hunting out the "two grains of wheat from the two bushels of chaff" in this case.

◆

We have for example looked over the detailed record of 240 tests of steel. We find that the modulus of elasticity of all the steel tested of whatever class is usually between 28,000,000 and 31,000,000 lbs., so that out of 40 tests, about 36 will run between these limits, and the other 4 generally not more than 1,000,000 lbs. beyond them. We also discover that one piece of plate steel, kind not stated, showed a modulus of elasticity of 35,455,000, and a piece of Bessemer steel a modulus of only 24,811,000. The "engineering public" might be interested to know whether these extreme results are due to the inaccuracy of tests by students or whether they are figures which are actually characteristic of the steel, and likely to be found at any time in any steel, although the practicability of finding them in any particular case is less than 1 in 100. What causes the high and the low modulus, and with what other physical or chemical characteristics are they coincident? The pamphlet, however, gives us not the slightest information on this subject, and in the absence of any other knowledge we can only conclude that the low modulus may be due to a flaw in the steel, and the high one to an error in measurement.

Now there may be other and highly valuable information hidden in this record of 240 tests, but if there is, who should know it, if not the professor that supervised the tests; and if he knows it, why not give the profession the benefit of his knowledge?

Turning over to the tests in the steam engineering department, we find some tests of an ejector and a pulsometer, and we look to see what information is given concerning the efficiency of these devices. We find that the ejector did from 500,000 to 1,200,000 ft.-lbs. of work per 1,000,000 B. T. U., while the pulsometer, with the same amount of heat, gave from 1,000,000 to 7,000,000 ft.-lbs. of work. Examining further, however, we find the statement that:

> The duty (foot-pounds of work done per 1,000,000 B. T. U. used) was calculated assuming that the heat put into the delivery water was not wasted. The heat used per pound of steam was taken as the total heat of the steam less the heat of the liquid at the delivery temperature.

A similar statement is made for the pulsometer test. We have to conclude, therefore, that the duty or efficiency given above is applicable only to the case in which either of these devices is used in a brewery, tannery, dye-house or some similar situation, where the heat imparted to the water by the steam is of value. But to the best of our knowledge, by far the more frequent applications of these instruments is in situations where the addition of heat to the water raised is of no importance whatever. Hence the efficiencies or duties above noted are not comparable with those of other low-duty water-raising devices, such as small, direct-acting steam pumps.

Perhaps the conductor of these tests had some good reason for the method which he chose; but if he had, why not state it? The fact is often lost sight of that the sole object of statistics, tables, diagrams, etc., is to convey ideas to the mind. The table or diagram which is published with no accompanying explanation of the truth which it shows, will in the great majority of cases be passed over by the busy reader unnoticed.

THE CONSTRUCTION OF STEEL CARS.

Probably the most important question which was considered at the recent convention of the Master Car Builders' Association, whose proceedings we reported in full last week, was the construction of steel cars. It is true that at the present time very few steel cars have been built; but the concensus of opinion of the best informed men engaged in rolling stock construction is that a change from wood to steel for the center sills (which structurally are the most important members of a railway car) is inevitable. We reprint in this issue the excellent report of the committee on this subject which was presented at the meeting, and our inset sheet shows the various designs of steel cars which accompanied that report. It is altogether likely that the subject of steel car design will be brought before a great many bridge companies and engineers engaged in structural iron work during the next few years, and we commend to them the principles laid down by the committee to govern such design. We venture to say that the designer who fails to observe any one of these rules, lessens by so much his chances of success. The only exception we would make in the list of ten requirements which are laid down by the committee, is that in the specification for riveting, it would have been better to have likened the quality of workmanship required to first-class bridge work instead of to boiler work.

On the other hand, some of the points touched upon by the committee seem to deserve greater emphasis. We may note for example the recommendation that truss rods should be dispensed with, and we may add to this that the main members of the under frame should be straight girders. The car frame may well be likened to a bridge. It is a continuous girder resting on two supports, some 20 ft. apart, and its end overhanging these supports about 7 ft. No engineer building a girder bridge for such a span would think of using truss rods beneath it, nor would he at the present day attempt to use anything but a straight beam or girder. Exhaustive tests with steel cars already constructed show that they stand up under loads 50% in excess of those they were designed to carry with exceedingly small deflection. There is, therefore, no need, either for strength or stiffness, to complicate the construction by using either trussing or by adding members beneath the frame at the center to aid the beams to carry their load.

Another recommendation of the committee which deserves emphasis is that with respect to making the center-sills of the car its backbone, so to speak. It is evident that the load which the car frame has to carry may be supported either by a series of, say, four to six shallow beams running parallel to each other the length of the car, and spaced an equal distance apart, or the bulk of the metal can be concentrated in two deeper beams at the center with lighter beams on each side. Of these two types of construction, the latter is the one evidently favored by the committee, and the reasons will be evident to anyone who has studied the forces which are exerted in a serious railway wreck. These deep beams have much more stiffness as well as strength than the shallower construction. In a collision these beams will be subjected to end compression, and will act as columns. A heavily loaded car might, in this way, it is conceivable, be subjected to a strain which would give it a permanent sag at the middle, and it will be more likely to suffer in this way the shallower the beams with which it is made. Again, the buffing shocks, which are the most serious the car has to sustain in service, will, if the metal is concentrated in the center sills, be transmitted through the train, with less strain on the connections between the center and side sills than would be the case if all the sills were of uniform depth.

We have alluded to the very great strength of steel car under frames. The Universal Construction Co., of Chicago, which has actively taken up the promotion of steel car construction has piled upon the frame of one of its cars of the Pennock pattern of 80,000 lbs., nominal capacity 126,000 lbs., 140,000 lbs., and finally 159,200 lbs., this last load deflecting it only ⅝-in. at the center. To make these tests the car body was supported not on its trucks, but on special blocking. It is evident from this that steel car under frames may and probably will be designed to easily carry much greater loads than are carried by any car now in regular service. A barrier is thus removed which has hitherto stood in the way of the economical construction of cars of very large capacity, and it is proper to inquire what are to be the results. What limit are we to set to the capacity of freight cars? It is but a very short time ago that the 60,000 lbs. car was considered an innovation of doubtful propriety. Now, every railway which handles great quantities of bulk freight at a low cost endeavors to move it in cars of this capacity. Again, the 80,000-lb. car is hardly in the future. Already a standard axle journal box, etc., for cars of this capacity has been designed by the Master Car Builders' Association, and the roads that handle coal and iron ore are ready to use it. The use of steel underframes will certainly mean an impetus toward the construction of cars of this capacity, and larger capacities, for whereas the cost of, say, a 40,000-lb. car would be much more if built in steel than in wood, when it comes to a car of 80,000 or 100,000 lbs. capacity, the difference in cost tends to disappear on account of the great amount of timber of first-class quality which it is necessary to put into such a car.

Again, the introduction of steel underframes is likely to mean another extension in the length of freight cars. An increase in length is, in fact, necessary, if we are to go beyond 60,000 or 80,000 lbs., for only the heaviest classes of freights can be loaded beyond this limit. There is a demand for an increase in length also from the shippers of bulky freights, who want longer cars in order to reach the allowable limit of weight.

Now, in view of these manifest tendencies, it is true that the question was asked whether a material increase in the length or carrying capacity of freight cars is desirable and should be permitted. Are 40 ft. freight cars and cars of 100,000 or 120,000 lbs. capacity going to cheapen the cost of rail transportation, or can they be safely permitted?

The question of safety deserves first consideration. We have seen that the car frame can be made strong enough for all demands, and metal truck construction also enables us to design a truck to carry any desired load. Axles, too, can be made of any size; but when we come finally to the wheels, it would appear as if some limit might be set. The American railway freight car is likely to have eight wheels and no more for a long time to come, and those wheels are likely to be made of chilled cast-iron and nothing else, so long, at least, as the product of car wheel foundries is sold at such astonishingly low prices. Chilled cast wheels are now running by thousands under loads per wheel reaching 10,000 to 12,000 lbs., and some are loaded, we presume, to 13,000 lbs., or even more. How much farther can we go? Is 15,000 or 18,000 or 20,000 lbs. a safe load for a chilled cast-iron wheel? Where shall we set the limit? That a limit there must be, somewhere, must, we think, be conceded. The thickness of a car-wheel flange is fixed and cannot be increased. The bearing surface between the rail and wheel, too, cannot be altered, save in a long term of years, for a freight car may go with its load anywhere, over rails of any section, from 100 lbs. down to, perhaps, 35 or 40 lbs., on some remote road. It will doubtless occur to many of our readers that if the wheels do not set a limit to the capacity of freight cars, the condition of rails and bridges on some railways will be likely to stop the progress of cars of excessive capacity at some point in their journey.

If an 80,000-lb. car weighs 35,000 lbs. empty and we allow for safety that it may be overloaded 10% when a consignment of steel rails or bridge iron comes along, such a car loaded may have a total weight of 123,000 lbs., or, say, 15,000 lbs. per wheel. A car of 100,000 lbs. capacity weighing 40,000 lbs. would increase this to nearly 18,500 lbs. If this is not near the limit which should be placed on the use of cast-iron wheels run at modern freight train speeds reaching at times 40 miles or even 50 miles per hour, then it must be uncomfortably near it. We are aware that the cast-iron wheel has done wonders; to it in no small degree is due the astonishingly low cost of moving freight in this country; but when engine driving-wheel loads exceeded the limits which were common a dozen years ago, cast-steel and wrought-iron centers began to displace cast-iron; and steel-tired wheels have very generally displaced chilled wheels under engine trucks. It is reasonable to believe, therefore, that there is a safe limit, not very far ahead, to the load on a chilled wheel.

But we must pass to the question of economy. A vast deal has been said, and truthfully said, of the reduction in the cost of freight transportation, due to the increase in car capacity; but at the same time it is well to recall that for general interchange service there is such a thing as too large cars. For local freight service on a very large number of railways the 30,000-lb. car is more economical than any larger size. The advantage of the 60,000-lb. car lies in the handling of bulk freights, or in general wherever full car loads and plenty of them can be had. For picking up local freights on small branch lines, cars of less capacity are, it is very certain, more economical.

To as large an extent as possible the railways meet these conclusions by keeping their old, light-weight cars in local service, and the newer, larger cars on the through freights; but this distribution can only be partially made. In times of car famine, such cars as are on hand are sent where the demand is most urgent, and necessarily go through with their loads. In general, then, the question what is the limit to which cars should be built for use in general interchange is a question deserving attention. If it is admitted that for a large percentage of the traffic of the country the 60,000-lb. car is too large for the best economy, does it not follow that we have gone far enough in the direction of enlarging the capacity of cars for use in general interchange?

If the coal carrying roads, the ore roads, or the roads moving great train loads of grain can employ 80,000-lb. or 100,000-lb. cars with profit, as seems altogether likely, let them build such cars, use them in their own traffic, and keep them on their own routes. To put such cars into general interchange service, however, would appear to be against the best interests of both the owner and the user and it will doubtless be avoided if the matter is correctly understood. The question relating to the size and capacity of cars for general interchange service were discussed in our issue of March 12.

As for an increase in the length of freight cars it is very doubtful whether an increase in the length of cars for general interchange service would be a real gain. Doubtless for the shipment of bulky freight a gain would be made; but if a car is to go out and roam over the country carrying now furniture, now flour, now machinery, etc., etc., it is better to design it for general service than to give it a size or capacity which increase the percentage of dead weight hauled during a large part of its life.

There are many other problems in connection with steel car construction which deserve study; but space permits us to speak of only one more. We have alluded already to the buffing shocks which a car body has to sustain. There seems reason to believe that if the time comes when solid trains of steel frame cars are run the shocks due to buffing will be much more severe, both upon the lading and upon the drawgear, than at present, unless some means are taken to absorb them.

It is a matter of common knowledge that wood absorbs shock in a much greater degree than iron. What part of a buffing blow is taken up by compression of the car sills is unknown, but it seems reasonable to believe that it may be a good deal. Besides this we have the compression of the end sills, draft sills, etc., at the points where the iron members that receive a blow are attached, to aid in absorbing the impact.

With a steel underframe, on the other hand, the shock received at one end of the car will be transmitted through practically solid metal to the other end. Suppose a 50-car train of steel cars running through sags and over summits. Will not the couplers between the cars be hammered to pieces if they have to resist the entire effect of the blows? Or, on the other hand, suppose the couplers are protected, as they should be, by iron buffer-blocks. Will not the shocks that will result tend to displace and injure the lading to a greater extent than now?

We make these merely as suggestions of points that deserve consideration in studying the general problem of steel car design. If it is found that the shocks do occur, as we have surmised, it may be found necessary to adopt some special form of spring or friction buffer to absorb shock between the cars, or even to use wooden buffer blocks, which could be easily and cheaply replaced when battered to pieces, instead of cast-iron. That the difficulty could be met in some such way, should it be found necessary, we do not doubt.

LETTERS TO THE EDITOR.

Garbage Disposal in England.

Sir: In the Engineering News of June 25, 1896, Mr. Rudolph Hering gives some very interesting progress reports of the operation of the garbage destructors at Berlin.

The tendency of modern practice in European cities for the disposal of city refuse is growing toward cremation as the safest and least expensive method. The city of Hamburg, directly after the terrible cholera epidemic of 1892, found itself placed in a peculiar and trying position. On account of the danger of infection from cholera germs which might be lodged in the garbage and house refuse, nobody could be found who was willing to receive it, as had been done before; and the city was therefore driven to provide some means for speedily and economically getting rid of it. Destruction by fire offered them the only solution, and as a result their present efficient and compact plant was evolved from the studies made under the direction of their Chief Engineer, Mr. F. Andreas Meyer. At the time of my visit to this plant, in November, 1895, only six cells were in operation, but the results from these were so encouraging that thirty new cells were under construction, and, I understand, have since been finished.

Many other continental European cities are debating this question, and watching the results of the Hamburg and Berlin experiments.

In Great Britain destruction by fire is the universal practice for the inland towns and for many seaports as well. There are more than 47 towns having destructors with a total of over 500 cells. The list can not be made complete, as many of the plants are constantly adding new cells as they are needed. Manchester has 68 cells,* Leeds, 50 cells; Birmingham, 37** cells; Bradford, 35, and so on.

The Hamburg plant is one of the largest garbage destruction plants in the world, and has a greater number of cells in one combination than any other.

The experiments in Hamburg, the results of which are not yet made public, promise to be very interesting and valuable. They go into the determination of the proper dimensions to be given to the various parts of the furnaces and flues to produce the best results. They include, among other things, a determination of the quantity of air required for the combustion of a ton of garbage, pyrometer tests and anemometer and barometer tests of the draft below and above the grates, as well as in the flues and stacks; also the relative efficiency of combustion with steam draft and with air blast. With either of these forms of artificial draft the quantity of oxygen supplied to the fires can be regulated at will, the difference between the two being in the amount of moisture supplied with the draft.

The process of burning is entirely chemical in action and is most complete when the conditions are proper for just a sufficient supply of oxygen to the fire and when the sections of the furnaces and flues are just sufficient to remove all the products of combustion, as they are formed. It is the province of the Hamburg experiments to determine some of these factors so that the designing of destructors may be based on scientific investigation.

The Hamburg destructors are built by the Horsfall Company, under their patents, and embody many improvements suggested by the Hamburg authorities, as a result of their studies.

In Mr. Hering's article, referred to above, the analysis given in the first Berlin progress report, for English refuse, might be considered as representative of the composition of the average ash-bin refuse of England. It is the analysis made by Professor Forbes of the Paddington refuse. Below is given Mr. Joseph Russell's* analysis of the average composition of the London ash-bin refuse, which I have arranged in the same manner as that given in the Berlin analysis, for purposes of reference; it will be seen that the London refuse is exceedingly rich in the products of imperfectly burned fuel; even more so than that given in the Berlin report for English cities:

Coal and coke	.84
Breeze (cinders and ashes)	63.69
Paper	4.28
Rags	.39
Bones	.48
Straw and other fibrous material	3.22
Vegetable, mineral, etc	4.61
Fine dust	19.51
Broken glass	.47
Iron	.21
Broken crockery	.55
Tins	.79
Bottles	.96
	100.00

The city of Leeds, in June, 1894, made a series of interesting tests of their destructors to determine their capacity and what it would cost to burn different quantities of garbage per day.

The results of these tests are set forth in a very interesting paper read before the Public Medicine Section of the British Medical Association, Aug. 2, 1894, by Mr. J. Spottiswoode Cameron, M. D., D. Sc., etc. It was published in the "British Medical Journal" and also in "Public Health," November, 1895.

A short abstract from this paper may not be uninteresting here. Before giving this extract, however, it may be well to state the disposition which they make of the different classes of city wastes. The horse droppings on the streets are largely cleaned up by farmers' lads sent in for the purpose. Each has a small cart and a pan and brush and the city allows them the privilege, without cost to either party. What these lads do not collect the city gathers up and mixes with the stuff from pans and closets and sells it for manure. The sweepings from the paved streets they take to certain localities and stack in piles to use as a binding material for the surface of newly macadamized roads. Sewage sludge they pump into pies about 50 × 60 and 2 ft. deep, surrounded by an earthen embankment. The water is allowed to drain and then the farmers come in and take the sludge away. The city used, formerly, to get five shillings a ton for this partially dried sludge. After a while they were glad to get one shilling for it, then sixpence, and now they are glad to be able to get rid of it without expense. The ash-bin refuse is taken to the destructors and burned, together with the refuse from markets and manufactories. The sorting of the materials at the destructors is done by hand and consists merely of removing the pieces of iron and other large incombustible materials.

The following is a description of the cells in which the tests were made, taken from Dr. Cameron's paper:

> The cells are placed back to back and fed from the top. The material passing over a bull-nose division to the two sets of cells, passes on to the concave side of an arc of a circle of fire brick. At the lower part of the curve the material reaches the fire-bars. These are sloped at an angle of about 30° and have an area of 7 ft. wide by 5 ft. long. The walls of the furnace are lined with fire-brick and just above the bars a strip of iron is fixed, but not in contact with the brickwork, to prevent the clinkers from fusing into the latter.

Underneath the fire-bars steam jets are introduced, two to each cell. These jets are made of two frustums of cones joined at the small ends, at which point they are 6 ins. in diameter; at the larger ends they are 9 ins. in diameter; the total length being 3 ft. The jets of steam vary in size from ⅛-in. in diameter to ½-in., with the boiler pressure of 60 lbs. per sq. in. Dr. Cameron continues as follows:

> In 1891 experiments were made at the Kidacre St. destructor to ascertan, amongst other things, what the difference in temperature was with the steam jets and without, with the following result: The experiments extended over two periods of 24 hours each, similar material being used on each occasion (19 hours dry ash-bin refuse and five hours wet ash-bin refuse), and temperatures taken hourly. It was found that the ten cells burned 6.2 tons per cell without, and 6.7 tons per cell with steam jets. The same number of men were working in each case. The temperature without the jets averaged 1,118° F., counting three observations when the pyrometer index touched its maximum as 1,500° F. With the jets the average was 1,464° F., but these included 17 observations when the pyrometer could register no higher. It is possible that the excess of temperatures of 346° F. would have been more like 500° if we could have registered it.

These temperatures are presumably in the cells, although the record of the experiments does not say so.

In Liverpool, Mr. H. Percy Boulnois writes me that a set of temperatures recently taken in his destructors gave the following values:

	Degrees F.
Temperature in the cells	900 to 1,000
In flue close to cells	900 " 1,000
In flue before cremator	600 " 700
In cremator	1,500 " ...
In base of chimney	675 " ...

They have a natural draft only, from a tall chimney.

Quoting again from Dr. Cameron's paper on the tests at Leeds:

> The amount of work done by our destructors in 1894 was equivalent to the burning of 63,132 loads of rubbish, weighing 65,151 tons.* Some of the cells were not working full time, but the quantity named was burned in 11,644 cell-days, which is equivalent to nearly 5.6 tons per cell per day.

The experiments made in June, 1894, by Messrs. Darley & Putman, at the request of Mr. Hewson, City Engineer, were conducted under the following general conditions:

> The furnaces . . . had a grate area per cell of 35 sq.ft., were in full go, and were clinkered immediately before the commencement of the tests. The tipping floor was cleared; all the material placed upon it afterwards was weighed, the material at the end of the experiment being weighed and deducted from the gross amount placed there. The clinker removed was also weighed, but no computation was made as to the increase or decrease in the amount of flue dust. The experiments lasted for either 12 or 24 hours each, and ended with a clinkering of the cells. The wages were calculated at the rate of five shillings per working day of eight hours. The steam jets (used in all the experiments but one) were two for each cell.

Experiments in 1894 with Destructor Cells at Leeds, England, by Messrs. Darley & Putman.

[1] Figures for cost have been reduced to American money by allowing 25 cts. per shilling, and 2 cts per pence. The tons are doubtless long tons. [2] Frequently 2,000° F.; i. e., melted copper.

> The general lesson from these experiments, not carried out for the purpose of exploiting any patent, but merely to test our own existing plant, is to the following effect: The amount consumed per cell increases with the frequency of clinkering, but the cost per ton burned is increased at a more rapid ratio. The frequency of clinkering can be rendered practicable by increasing the rapidity of combustion. This can be done by steam jets, and the most frequent clinkering and the greatest amount burned per cell was accomplished with two ½-in. jets at 60 lbs. boiler pressure. The cost in firemen's wages, however, in obtaining these tremendous results (26¾ tons per cell per day) was nearly 53% higher per ton burned than when the clinkering was every two hours and the consumption ten tons per cell per day. It must also be added that the wear and tear of the plant is much greater at the higher output, though exactly in what proportion the experiments do not enable us to say. On the whole, the high output method of working the destructors is not economical.

The writer visited these works (Leeds) last December and was informed that the most economical rate of combustion appeared for them to be about 6½ tons per cell per day, but that the rate would vary greatly with the varying composition of the refuse. On market days, for instance, it would not burn nearly so well as when it was ordinarily dry and contained much coal. The stuff which they were called upon to dispose of varied considerably; sometimes they would have large quantities of spoiled canned goods and occasionally large quantities of condemned meat. On one occasion they had a lot of condemned hogs which they put into the furnace whole. They burned very readily, a whole hog disappearing into ashes in about half an hour.

In Cambridge, England, the writer visited the new destructors built under the direction of Mr. John Wood, C. E., of Liverpool. These furnaces are remarkable in the results obtained in the development of power from the burning of garbage. It must be said that the composition of the garbage is very favorable for such purposes, containing, in the writer's opinion, a large quantity of paper, straw, rags, wood, unburned coal and cinders. The destructors are arranged so as to develop the greatest possible heating qualities for the purpose of generating steam, to pump the sewage of the city to the farm, two miles distant, where it is spread over the surface. The destructors are alternated with Babcock & Wilcox boilers in such a manner that each boiler has two destructors to furnish it heat. Cremator fires can also be built in the fire-boxes under the boilers, in order to destroy the unconsumed gases resulting from the loss of heat in heating the boilers and to supply extra heat for the boilers if necessary. The work which they get from their plant is sufficient at present to pump 1,250,000 gallons of sewage per day, with a lift of 40 ft. The pumps are in duplicate, made by Hawthorne, Davey & Co., of Leeds, and are of about 70 HP. each. They run now on 50 lbs. steam pressure, which is generated by the heat from two destructors. They run the pumps in two shifts of six hours each per day. They do not get enough garbage at present to run all day and night too, and so they are obliged to use coal under the boilers at night until the morning collections come in. The cells are fitted with Boulnois & Brodie's patent charging cars. They burn from 8 to 10 tons per day per cell, with forced draft, supplied by a fan blower forcing air under the grates. They develop about 30 HP. per cell in this way. Southampton also has recently made plans for increasing its present destructor plant with four new cells arranged on the same lines as these Cambridge destructors, and they are anticipating an addition of 120 HP. therefrom.

James H. Fuertes.

*This is equivalent to about 325 lbs. of refuse per person per annum.—(J. H. F.)

CENTRIFUGAL PUMPING.

By J. Richards, San Francisco.

The writer, who has for a good many years watched with diligence the design, construction and effect of machinery for raising large volumes of water, finds that in this, as in all branches of constructive art, the course of evolution is not regular or always progressive, but is sometimes backward.

The best field for observation has been in the Netherlands, in so far as permanence or durability and also efficiency are concerned, but even there, owing to an intense conservatism, we find plants of questionable merit when judged in the light of present practice. The great pumps by Farcot, of Paris, erected about five years ago at Khatatbek, on the Nile, in Egypt, have various features that have much increased the cost of construction without any perceivable gain in the qualities of efficiency and durability, and they are certainly no improvement on the great plant at Ferrara, in Italy, erected by J. & H. Gwynne, of London, in 1873.

This plant, in northern Italy, drains 200 sq. miles of swampy lands, and raises the enormous quantity of 2,000 tons of water per minute, equal to 72,960 cu. ft., or more than 500,000 gallons. This, if flowing in a canal at the rate of two miles an hour, would form a stream 103 ft. wide and 4 ft. deep. There are eight pumps of 54-in. bore, driven in pairs by four compound condensing engines.

The drainage of Haarlem Meer before centrifugal pumping had a place in the methods available, and the drainage of the Zuider Zee, now going on with centrifugal pumps, must ever remain notable examples of what can be done in the drainage of valuable lands when unstinted capital and high skill are brought to bear; but there is another standard that must be set up when the lands are less valuable and their permanent reclamation a problem, as is the case in the great valleys of California. This latter California practice, now quite extensive, has added a good deal to the art in the way of attaining and even exceeding the efficiency of Old World methods with machinery in every way more simple and less expensive.

Dividing the cost by foot-pounds of duty, or volume and head, the cost of plants to raise from 20,000 to 100,000 gallons per minute in California is not more than two-thirds of what machinery of like capacity costs in Europe.

Some evidence of the skill attained in this branch of engineering on the Pacific coast is seen in the contract lately awarded to the San Francisco Bridge Co. for a pumping plant at New Orleans to raise 18,000 cu. ft., or 135,000 gallons per minute against a head of 12 ft.

The various large plants in the Sacramento and San Joaquin valleys operate at an efficiency that will average between 60 and 70%. In some cases this has been exceeded. Notably in the case of a plant recently erected at Marysville, Cal., on the Feather River, Sacramento Valley, by Messrs. W. T. Garratt & Co., of San Francisco, who sent the accompanying report of a test made in February last.

Test of Centrifugal Pumping Plant, at Marysville, Cal.; Feb. 9, 1896.

Diagrams of the compound engine used are shown in the accompanying cut, Fig. 1.

The pump was made under a patent granted to the writer in 1887, and operated in the method indicated in the diagram, Fig. 2.

The curves, it will be seen, are natural and easy, while the whole construction lends itself to stability and ready adoption.

Water enters at one side of the pump through the suction or inlet pipe A, and is set in revolution by the vanes B, the number and curves of which are made to suit the head and other working conditions.

By entering the water at one side, it will be seen that curves are more flat and the course of the water is direct in comparison with a double inlet pump; the impeller is balanced the same as if like duty was done on each side of the plate or disk C.

On the back of this disk is a supplementary set of vanes, D, shallower in depth, the function of which is to set up centrifugal action at the back nearly the same as on the front or the working side of the disk C.

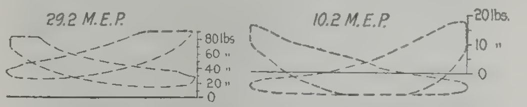

Fig. 1.—Indicator Diagram From Ide Compound Condensing Engine used with Richards' Centrifugal Pump.

As, however, these vanes D are a little shorter than the main ones B, there is a slow circulation over the periphery of the disk C, permitted by the holes E, near the hub of the impeller, so the pump is as completely balanced as though it had a forked or double suction and evades several objections that apply to that type.

The advance in centrifugal pumping in California has not been so much in the adaptation to large volumes, such as have been presented elsewhere, as in operating against high heads or pressures to an extent not attempted in other places.

The Edison Light & Power Co., of San Francisco, has for several years past raised salt water for condensing purposes 70 feet high through pipes 3,000 ft. long. The amount of water thus raised serves for 8,000 HP., and the main pipes are of 24 ins. bore.

In irrigating plants where water is pumped from gravel strata, the heads are from 60 to 100 ft., and in some cases have been more. At first such pumps were made compound, with two or more impellers, so as to avoid the high speed of revolution required with a single impeller or runner, but this method has been abandoned because of the loss of power, and now such pumps are made single in all cases, the water being carried through as much as 600° or even 800° of revolution before it leaves the vanes, without any such loss as computation assigns for this method of operating.

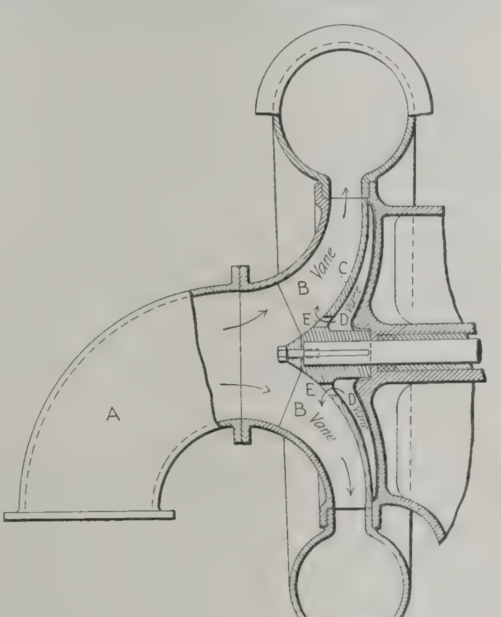

Fig. 2.—Section of Centrifugal Pump Designed by Mr. J. Richards in 1887.

Speaking of the resistances in compound centrifugal pumps due to varying velocity, agitation, deviations in the course of the water, etc., and as an example of "falling back" in the art, the diagrams comprising Fig. 3 are submitted to the readers of Engineering News for analysis.

The scheme can be followed out without the aid of special references. The water is first driven out by fans or impellers revolving in the circular chamber a, then through the apertures e, and its rotation is stopped by the radial vanes f, shown in dotted lines in the same figure. It then passes back to the center and into a second impeller, and is driven out again through a second set of apertures g and so on to discharge at c. The drawing shows but two units or elements, but the machines are made triple.

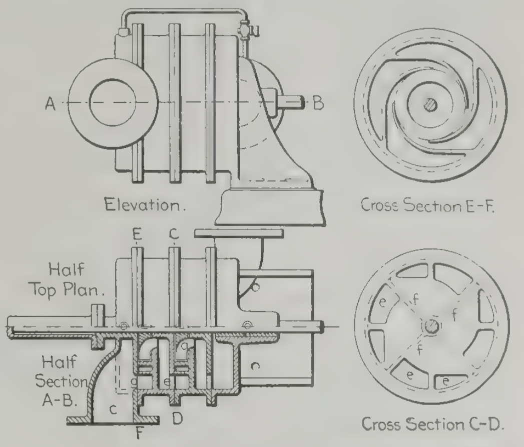

Fig. 3.—A Backward Step in Centrifugal Pump Design.

OHIO STATE LAW REGULATING THE INTERLOCKING OF RAILWAY GRADE CROSSINGS.

The following is the text of a law just passed by the Ohio State Legislature to regulate and control the protection of railway grade crossings by interlocking signals. In Engineering News of Feb. 6, the operation of a similar law in the state of Illinois was discussed at some length, and in another column of this issue some of the more salient features of the Ohio law are considered.

Section 1. Be it enacted by the General Assembly of the state of Ohio, that when in case two or more railroads, or a railroad and an electric railroad crossing each other at a common grade or any railroad crossing a stream by a swing or drawbridge, shall, by a system of interlocking, or by other works or fixtures, to be erected by them, or either of them, render it safe for engines or trains to pass over such crossing, or bridge, without stopping, and such system of interlocking works or fixtures shall first be approved by the commissioner of railroads and telegraphs, and a plan of such interlocking works or fixtures, for such crossing or bridge, designating the plan of crossing, shall have been filed with such commissioner, then, and in that case, it is hereby made lawful for the engines and trains of such railroad or railroads, to pass over such crossing or bridge without stopping, any law, or the provisions of any law, now in force to the contrary notwithstanding, and all such other provisions of law contrary thereto are hereby declared not to be applicable in such case; provided, that the said commissioner shall have and is hereby given power in case such interlocking system or other fixtures, shall, in his judgment, prove to be unsafe or impracticable, to order the same discontinued, opportunity first being given the persons or company operating the same to be heard before said commissioner as to the propriety of such order. In case such order is made and enforced, the existing statutes relative to stopping at crossings shall apply until such time as a device approved by said commissioner is substituted.

Section 2. That in case where the tracks of two or more railroads, or the tracks of a railroad and an electric railroad cross each other at a common grade in this state, any company owning any one of such tracks, whose managers may desire to unite with others in protecting such crossing with interlocking, or other safety devices, and shall be unable to agree with such others on the matter, may file with the said commissioner a petition stating the facts of the situation and asking said commissioner to order such crossing to be protected by interlocking, or other safety devices; said petition shall be accompanied by a plan showing the location of all tracks and switches, and upon the filing thereof notice shall be given to each company or persons owning or operating any track involved in such crossing, and the said commissioner shall thereupon view the site of such crossing and shall, as soon as practicable, appoint a time and place for the hearing of such petition. At the time and place named for hearing, unless the hearing is for good cause continued, said commissioner shall proceed to try the question of whether or not the crossing shall be protected by interlocking or other safety devices, and shall give all companies and parties interested an opportunity to be fully heard; and after such hearing said commissioner shall enter an order upon a record-book, or docket, to be kept for the purpose, granting or denying such petition; and in case the same is granted, such order shall prescribe the interlocking or other safety devices for such crossing and all other matters which may be deemed proper to the efficient protection of such crossing, and in such order the commissioner shall designate the proportion of the cost of the construction of such plant, and the expense of maintaining and operating the same, which each of the companies or persons concerned shall pay, and shall also fix the time within which such appliance shall be put in, such time, however, not to exceed 90 days from the making of such order.

Section 3. In case, however, one railroad company or an electric railroad campany shall hereafter seek to cross at grade with its track, or tracks, the track, or tracks, of another railroad, the railroad company, or the electric railroad company, seeking to cross at grade shall be compelled to interlock such crossing to the satisfaction of the said commissioner, and to pay all cost of such appliance, together with the expense of putting them in and the future maintenance and operation thereof. Provided, this act shall not apply to crossings of side tracks only.

Section 4. Whenever interlocking or other safety devices are constructed and maintained in compliance with Section 2 or 3 of this act, then and in that case it shall be lawful for the engines and trains of such railroad, or railroads, and the cars of such electric railroad to pass over said crossings without stopping; any law or the provisions of any law now in force to the contrary notwithstanding; and all such other provisions of law contrary thereto are hereby declared not to be applicable in such case.

Section 5. Any person, company or corporation refusing or neglecting to comply with any order made by the said commissioner of railroads and telegraphs in pursuance of this act shall forfeit and pay a penalty of five hundred dollars per week for each week of such refusal and neglect, the same to be recovered in an action of debt in the name of the state of Ohio, and to be paid, when collected, unto the county treasurer of any county in which such suit may be tried.

Section 6. This act shall take effect and be in force from and after its passage.

THE POWER PLANT AT FRESNO, CAL.

The San Joaquin Electric Co. has recently completed the installation of an electrical plant, driven by water power, to furnish light and power to the city of Fresno. The power is derived from water brought from the headwaters of the San Joaquin River. This source of supply is between 40 and 50 miles from Fresno, the generating plant itself being located 35 miles away. The water is taken from the north fork of the San Joaquin River at an elevation of 2,500 ft. above sea level, and is conveyed partly by means of a channel cut in the solid rock and partly by flumes, to a natural reservoir. This reservoir covers eight acres 10 ft. deep, and is intended as a safeguard against occasional repairs to the canal. There are ample sites for other reservoirs should an increased demand for water or extended drought make them necessary. An emergency canal leads from the supply, around the reservoir, to a connection with the pipe down the mountain, so that the reservoir, in case of accident, can be dispensed with entirely. The steel pipe which leads from the reservoir down to the power house is 4,100 ft. long, and gives a difference in level of 1,410 ft.; at the bottom it is 22 ins. diameter, with a ⅝-in. shell. The size is increased until at the reservoir it is 24 ins. in diameter, and the thickness of shell is reduced to ¼-in.; it is anchored to the solid rock of the mountain side by means of wire cables. The San Francisco "Chronicle" states that the pipe was built from both ends, and that it was very difficult to insert the last joint, owing to a variation of six to ten ins. in the length of the pipe. The junction was finally effected at 3 a. m. The outside of the pipe is protected by a coating of asphaltum; after the pipe was completed a workman was let down through its entire length, for the purpose of painting the inside joints.

At the lower end of the pipe is a large steel receiver, from which project the phosphor bronze nozzles for directing the streams against the water wheels. This receiver is 57 ft. long, by 30 ins. diameter of ¾-in. steel with butt-strap joints, and is designed to stand a working pressure of 800 lbs. per sq. in. The power house at the bottom of the hill is built of native granite, with a wooden roof. It is 75 × 30 ft., and is built on bed rock. The receiver and water-wheels are outside the main power house, the shafts passing through a heavy granite wall which keeps all the water and moisture out of the dynamo room.

The water wheels are of the Pelton Water Wheel Co.'s make, 57 ins. diameter, each capable of developing 500 HP., at 600 revolutions per minute, under an effective head of 1,410 ft. The wheels are constructed with steel plate centers and bronze buckets, and are fitted with flywheels 5 ft. diameter. Separate wheels are provided for the exciters.

Pipe Line and Power House of the Water Power and Electric Plant for Fresno, Cal.

The dynamos are of the General Electric pattern, direct connected to the motor shafts, and of 350 K-W. capacity at 600 revolutions per minute. The pressure at the dynamos is 700 volts, and is transformed to 11,200 for transmission to Fresno. A pressure of 10,000 volts is received at the end of the 35-mile line, where it is reduced to a commercial pressure. The entire cost of the plant is said to be only about $200,000. We are indebted to the General Electric Co. for the accompanying cut.

THE CORONER'S VERDICT ON THE VICTORIA BRIDGE DISASTER.

Since our issue of June 18 we have received the report (published in the Victoria "Daily Colonist") of the coroner's jury which investigated the Victoria bridge disaster, in which 55 persons lost their lives. The facts in connection with this accident and the general verdict of the coroner's jury we published on June 18, but the investigation made by the coroner's jury and the full verdict which it rendered reveal so many object lessons with respect to how not to conduct a city's engineering work, that we reprint some extracts.

The following is the report of the testimony of Mr. E. A. Wilmot, the City Engineer, when recalled to the stand on the closing day of the investigation:

> He had not absolute charge of his department. It had been the custom of chairmen of the various city departments to give directions regarding works coming under them; in matters not considered to require particular knowledge of engineering the chairmen have not considered it necessary always to consult him. He had no letter of instructions defining his duties; he had made recommendations, sometimes to the street committee, that had not been carried out. He recalled one instance where his plans were interfered with; he had prepared plans for a bridge on the Lansdowne road and the work was not carried out according to them; the street committee had power to ignore his work. He had no power to carry out work irrespective of the council—the council reserved the right to dismiss his assistants without his consent. This had inconvenienced him sometimes, and he had not the same authority over his subordinates as if he appointed them himself. He had been consulted about the appointment of his subordinates, but not always. Cox, the city carpenter, was in the city's employ before witness became city engineer; streets, sidewalks and bridges all came under Wilson (Street Superintendent) now. Witness's duties were too numerous to allow him time to thoroughly inspect the bridges. There was more work for him to do than he could accomplish in office hours. He had never had a vacation since he had been appointed, not that he had been refused, but he had felt he had not time to take one.

The following is extracted from the Coroner's charge to the jury:

> The jury should consider whether or not any responsibility rested on the tramway company, if, when they increased the size of the cars they took no precautions. The company seemed neither to have consulted the city engineer nor to have tried to find out if the bridge was safe. Then the jury must find out if the bridge was maintained in a state of safety by those responsible for it. There was not the least doubt that the bridge had been utterly neglected from the time that it was built and there had been no proper inspection of it. Whose duty was it to keep the bridge in a state of safety? The mayor and council acted in exactly the same capacity as the government of the country, and so were primarily responsible for the safety of life and property in the city. Their responsibility was generally shifted to the shoulders of the servants under them, but in this particular instance there was quite a difference of opinion—some witnesses held that the responsibility of looking after the bridge fell on the city engineer, others that the city carpenter had it under his charge. It had been stated in evidence that the city engineer never had his duties explained to him or definitely defined, and moreover, it had been shown that he was completely under the thumb of the council and the streets committee, and it was shown that his recommendations to the council have at times been completely ignored. For instance, the probability is that if his advice had been taken about putting in iron floor beams when the bridge was repaired in 1892 there would have been no inquiry like this to-day. Under the circumstances the coroner could not see how the engineer should be held responsible. A man to be responsible must have full control of that for which he was responsible. As to the city carpenter, it was too absurd to hold him responsible for Point Ellice bridge. An ordinary mechanic could not be expected to do the work of a skilled engineer. Then again, had the city council taken any steps to have the bridge inspected? The only thing that could be found in this connection was a report by Cox (the city carpenter) last year stating that the bridge was in good condition; and as the city council seemed to be satisfied with that report, it seems to show that they looked upon Cox as responsible. As to the exact cause of the accident, whether it was a floor beam or a hanger to go first mattered not. The cause of the acident was undoubtedly the neglect to maintain the bridge in an efficient state to do the work put upon it.

The following are the facts of the verdict rendered by the jury of principal interest:

> The accident was the result of the sudden collapse of the eastern Whipple truss of the said bridge, and was caused by the weight of car No. 16 of the Consolidated Electric Ry. Co. and its immense load of passengers. which was in excess of the capacity of the bridge in question as originally constructed, and that the said Consolidated Electric Ry. Co. is guilty of negligence in not having taken proper precautions for the safe conduct of its passengers accordingly. It is the duty of all corporations of this kind to see that all roads and bridges over which it passes are in a safe condition.
>
> That car No. 16 was dangerously overloaded with passengers, and in the interest of public safety it is imperative that restrictions should be imposed upon the traffic of this and similar corporations in the future.
>
> That the city council having assumed control of the said bridge, it was manifestly their duty to the public to maintain it in a proper state of repair and efficiency, and to take steps to restrict the traffic of the said railway company within the limits of safety.
>
> If they do not possess this power legally, it was and is their duty to obtain this power by legislation.
>
> We desire to call attention to and to condemn the system of public works which has been and we believe now is in vogue in the public works department of the city. We find that the city engineer and heads of departments under him who should be held personally responsible for the good and efficient execution of the details of their department, are so hampered and interfered with by untechnical, elective superiors, that they are without au-

thority necessary to carry on their work, and are consequently without responsibility.

We further find occasion, in the interests of public safety, to call attention to the fact that the government department under which this bridge was conducted did not exercise proper supervision over the construction of same, particularly in the matter of ironwork. We find that the specifications call for weldless iron, but that the ironwork is in almost all cases welded, and in many cases of inferior quality, and that the factor of safety provided for in the specifications is an unknown quantity.

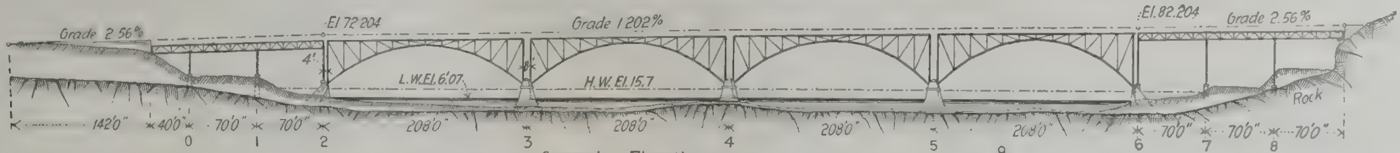
It is quite evident from the evidence produced before us, that the primary cause of the accident was the breaking of one certain iron hanger, resulting finally in the collapse of the bridge; said hanger being part of the original construction.

We find, therefore, that the Consolidated Electric Ry. Co. are primarily responsible for the accident, and that the city council is guilty of contributory negligence.

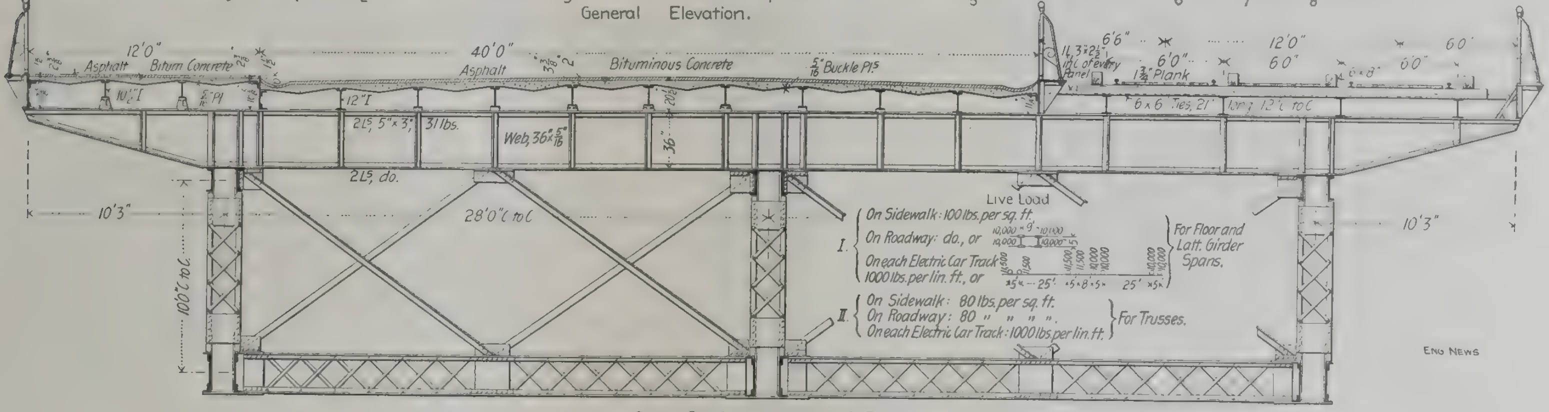
A NEW BRIDGE OVER THE SCHUYLKILL RIVER IN FAIRMOUNT PARK.

We show herewith a general elevation and cross-section of a new bridge which is to be erected across the Schuylkill River in Fairmount Park, Philadelphia, by the Fairmount Park Transportation Co., of which Mr. Russell Thayer, Jr., M. Am. Soc. C. E., is Consulting Engineer. Special attention has been paid in the design of the bridge to secure an artistic effect. The contract for the structure has been awarded to the Phoenix Bridge Co. The weight of metal work in the structure will be about 6,000,000 lbs., and the total cost, including foundations, is estimated at $375,000. It will be seen that the electric car tracks are entirely separated from the roadway, and that guard rails are provided beside each track. These features, and the manner in which the bridge is proportioned for its live loads, are of interest in connection with our editorial remarks on the Victoria bridge disaster in our issue of June 18.

We are indebted to Mr. John Stirling Deans, Chief Engineer of the Phoenix Bridge Co., for the drawing from which our illustration is reproduced.



General Elevation.



Cross Section at Center of Span.

NEW BRIDGE OVER THE SCHUYLKILL RIVER IN FAIRMOUNT PARK, PHILADELPHIA.

LOCOMOTIVE COUNTER-BALANCING.*

The purpose of adding counter-balance weights to the driving wheels of locomotives is to prevent or minimize the strains and vibrations caused by the momentum or inertia of the moving parts attached directly or indirectly to them. These are of two kinds, revolving parts and reciprocating parts. The revolving parts can be counter-balanced by weights attached to the wheel to which they belong. The reciprocating weights can only be balanced in one direction by adding weights to the driving wheels, as all weights added after the revolving parts are balanced over-balance the wheel vertically, exactly to the same extent that they tend to balance the recoprocating parts horizontally. This over-balance exerts a pressure upon the rail directly proportional to its weight and to the square of its velocity. At high speeds this pressure, which is added to the weight of the driver on the rail, may become great enough to injure track and bridges.

In consideration of the above, your committee have formed the rules which follow after full consideration of the following fundamental principles:

1. The weight of the reciprocating parts that are left unbalanced should be as great as possible, consistent with a good riding and smooth working engine.

2. The unbalanced weight of the reciprocating parts of all engines for similar service should be proportional to the total weight of the engine in working order.

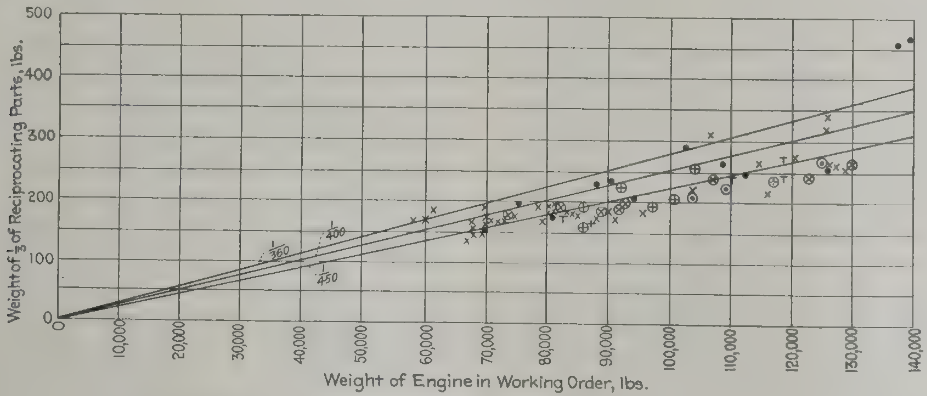
3. Total pressure of the wheel upon the rail at maximum speed when counter-balance is down must not exceed an amount depending upon the construction of bridges, weight of rail, etc., and when counter-balance is up the centrifugal force must never be sufficient to lift the wheel from the rail.

A majority of railways answering the committee's circular leave unbalanced one-third of the reciprocating parts. In order to see how nearly this method makes the unbalanced weight of the reciprocating parts proportional to the total weight of the engine, we have plotted on the accompanying diagram the relation between the unbalanced reciprocating weight on one side, and the total weight of 75 road engines in actual satisfactory service on seven different roads. On the same diagram are drawn lines, all the points in which are proportional to the total engine weights laid off on the horizontal. The first line marked 1-450 is drawn through about the average of all the points plotted, and indicates that the average unbalanced weight of the reciprocating parts on one side of engine as balanced on these roads is 1-450 of their total weight. The upper line marked 1-360 represents the ratio of unbalanced reciprocating parts on one side to the total engine weight, recommended by Mr. G. R. Henderson, Mechanical Engineer of the Norfolk & Western R. R., in an admirable report on this subject, made to Mr. R. H. Soule, about a year ago, and to which your committee is indebted for valuable data and suggestions. Mr. Henderson proposes the following formula for expressing the relation between the unbalanced reciprocating parts and the total weight of the engine:

$$Wr = \frac{Wt}{360}$$

Wr = the weight of the unbalanced reciprocating parts on one side:

Wt = the total weight of the locomotive in working order.



RELATION BETWEEN WEIGHT OF LOCOMOTIVE AND WEIGHT OF ITS UNBALANCED RECIPROCATING PARTS.

From the data obtainable, we believe this formula allows a greater proportion of the reciprocating parts to remain unbalanced than present good practice will warrant.

The intermediate line marked 1-400 on the diagram indicates the average maximum of unbalanced weight of reciprocating parts in locomotives now in service on various roads. From actual tests of locomotives so balanced in fast passenger service, we recommend it as a safe formula for the maximum limit of the weight of the unbalanced proportion of the reciprocating parts on one side.

In formulating the following rules it is assumed that the driving wheels are finished and mounted on their axles with pins in place.

In designing new locomotives the proper counter-balance weight should be calculated and cast into the wheel centers as follows: Place the center of gravity of counter weight opposite the crank pin as far from the center as possible, and have it come as near the plane in which the rods move as proper clearance will allow. To obtain weight of the reciprocating parts and detachable revolving parts, proceed as follows:

Reciprocating Parts.—Take the sum of the weights of piston complete, with packing ring, piston rod, crosshead complete, and the weight of the front end of the main rod complete. Weigh each end of rod separately supported.

Revolving Parts.—Weigh the back end of the main or connecting rod, and each end of each side rod complete, separately supported. The sum of the weights so found which are attached to each crank pin are the revolving weights for that pin.

Rules for Counter-Balancing Locomotive Driving Wheels.—1. Divide the total weight of the engine by 400; subtract the quotient from the weight of the reciprocating parts on one side as found above, including the front end of the main rod.

2. Distribute the remainder equally among all driving wheels, adding to it the weight of the revolving parts for each wheel. The sum will be the counter-balance required if placed at a distance from the wheel center equal to the length of the crank.

Counter-balance weights added to old wheels should be generally cast in two parts, fitted between spokes and securely bolted with the ends of bolts riveted over the nuts. Increased weight of counter-balance can be obtained when necessary by coring out cast iron and substituting lead, or in other ways replacing cast iron with a denser material.

Cautions and Limitations.—If we assume that the maximum speed in miles per hour of the driving wheel of a locomotive equals its diameter in inches, it can easily be shown (see Appendix) that if such wheel is over-balanced by an amount W, at its maximum speed, this over-balance will increase and decrease the wheel pressure on the rail each revolution 38.4 times W. Or if we denote such increase pressure by P, then P = 38.4 times W, or P = 40 W (nearly). Therefore, in order that the wheel shall never leave the rail, 40 times the portion of the weight of the reciprocating parts added to each wheel must not exceed its static pressure on the rail. To insure safety it should not exceed 75% of such pressure. Nor should this amount, when added to the static wheel pressure, exceed the safe maximum pressure allowed on track and bridges. Locomotives with rods disconnected and removed should not be hauled at high rates of speed.

---

*From a committee report presented at the annual convention of the American Railway Master Mechanics' Association.

Make reciprocating parts as light as possible.

Spread cylinders as little as possible.

E. M. Herr, W. H. Lewis, C. H. Quereau, S. P. Bush,
Committee.

Appendix.

We take the following from Mr. Henderson's report:

"To determine the centrifugal force, we have from Weisbach, Vol. I., page 609, the following formula:

$P = .00034\ U^2\ G\ R$

U = revolutions per minute,

G = weight in lbs.,

R = radius in ft.

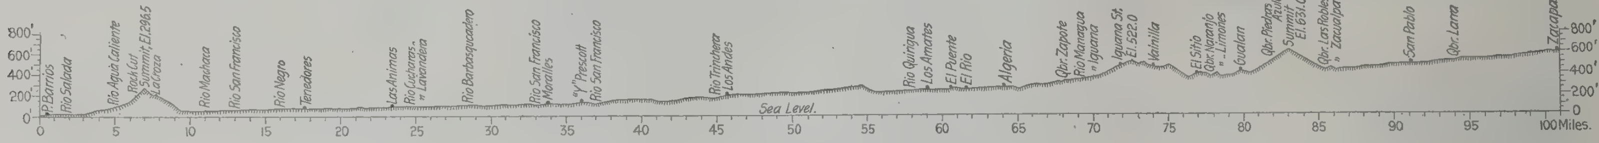


FIG 2.—PROFILE OF GUATEMALA NORTHERN RY.

Now let

s = speed in miles per hour,

d = diameter of wheel in ins.,

then

$$U = \frac{s \times 5{,}280 \times 12}{3.1416 \times d \times 60} = \frac{s \times 1{,}056}{d \times 3.1416} = 336\ \frac{s}{d}$$

and

$$U^2 = 112{,}896\ \frac{s^2}{d^2}$$

and, substituting, we have,

$$P = 38.4\ \frac{s^2}{d^2}\ G\ R,$$

and where

$$R = 1,$$

$$P = 38.4\ \frac{s^2}{d^2}\ G.$$

If we assume that the speed in miles per hour at its maximum equals the diameter of the wheel in inches, we have simply

$$P = 38.4\ G,$$

or say,

$$P = 40\ G."$$

* * *

SEWAGE DISPOSAL BY INTERMITTENT FILTRATION AND BROAD IRRIGATION AT BRISTOL, CONN.

The third town in Connecticut which has thus far made any attempt to treat its sewage before discharging it into some stream or other body of water is Bristol, Conn. Meriden led off with an intermittent filtration and broad irrigation scheme, and later Bristol has followed its example. Between the dates of putting these plants in operation a station for the manufacture of sodium hypochlorite by the Woolf electrical process was installed at Danbury, Conn., and this has been used to disinfect the sewage before it discharges into the river. The city has been ordered by the courts to keep the sewage out of the river after May 1, 1897.*

The work at Bristol has been done by the borough, the population of which was not separately returned by the last census. In 1890 the whole town had 7,382 inhabitants, against 5,347 in 1880. A gravity water supply was introduecd by a private company in 1895.

Early in 1892 riparian owners began to bring suits to restrain the discharge of crude sewage into a stream flowing through the town. The suits were withdrawn, on agreement that a sewerage and sewage disposal system should be built. During the year 1892, Mr. T. H. McKenzie, M. Am. Soc. C. E., now of Hartford, Conn., was engaged to make preliminary plans and estimates for a sewerage system, with recommendations as to the best methods of sewage disposal. This he at once did, but delays in securing legislation and preparing detailed plans prevented the execution of the work for about three years.

During 1895 there were constructed 9½ of the proposed 15 miles of sewers, and part of the land was prepared, the latter being put in use on Dec. 20. The separate system of sewerage was put in, with underdrains for collecting the ground water and discharging it into the nearest water courses. The sewer pipes have deep and wide sockets, and are in 3-ft. lengths. The joints were calked with oakum and then cemented. Mr. McKenzie states that as a result of this course but little ground water finds its way into the sewers, a matter of great importance where sewage is to be purified, as was discussed at length in our issue of Aug. 25, 1892.

The borough bought 80 acres of land, recommended by Mr. McKenzie, paying $35 an acre, or $2,800 for it. Six acres of land have been made into filter beds, and a portion of the irrigation area has been cleared of bushes and plowed.

The filter beds are composed of coarse sand and gravel. The sewage is distributed to them by means of 15 and 12-in. main carriers. Only a part of the underdrains have been put in, but these will be 8 and 6 ins. in diameter and 25 ft. apart. The irrigation area will not be underdrained. The six acres of filter beds and appurtenances, Mr. McKenzie states, will cost about $9,000.

Up to April 1, 1896, about 100 connections had been made with the sewers. It is expected that a portion of the irrigation area will be graded during the summer of 1896. Mr. Albert Munson is superintendent of sewers.

We are indebted to Mr. McKenzie for the greater part of the above information, some of it being taken from a paper by him in the last report of the Connecticut State Board of Health. Mr. McKenzie and Prof. Herbert E. Smith, Chemist of the Board, have been authorized to make studies of the work of the Bristol disposal area. Mr. McKenzie is the engineer member of the State Board of Health.

THE GUATEMALA NORTHERN RAILWAY.

One of the important railway projects now being carried out in Central America is the Guatemala Northern Ry., which extends inland from the port of Puerto Barrios, on the Atlantic coast (Gulf of Honduras), following the valley of the Motagua River, and being practically parallel with the Honduras frontier. This line was commenced by the government in 1883, when Gen. Rufino Barrios was President. After his death, in 1884, work was suspended, with only three miles of track laid. The enterprise remained dormant until 1893, when President Reyna Barrios entered into a contract with Mr. Silvanus Miller, M. Am. Soc. C. E., for the completion of the first 20 miles. Since then, by several contracts with Mr. Miller, the construction has been steadily continued, and the line is now open for traffic from Puerto Barrios to Gualan, 80 miles. In July it will be opened to Zacapa, 101 miles, and by October it is expected to be in operation to "El Rancho," 134 miles from Puerto Barrios. The road is intended to form a part of a transcontinental route, and will probably be completed to Guatemala City, about 200 miles, in 1898, connecting there with the Guatemala Central Ry., which is now in operation from that city to the port of San Jose, on the Pacific coast, a distance of 75 miles.

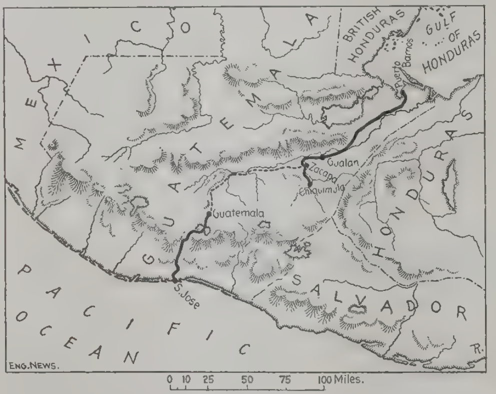

Fig. 4.—Map Showing the Guatemala Northern Ry. and Guatemala Central Ry.

The line has a gage of 3 ft. The track has 40-lb. rails for the first 18 miles, and 56-lb. rails for the rest of the distance, while the 40-lb. will soon be replaced with 56-lb. rails. There are turntables at Puerto Barrios, Los Amates, Gualan and Zacapa; also well equipped shops at Gualan, and a small shop at Puerto Barrios. A fine wharf has been built at this latter place, where ships of 5,000 tons have discharged their cargoes. The equipment includes 8 Baldwin locomotives, 1 parlor car, 13 passenger cars (including baggage cars), 30 box cars, 115 flat cars and 2 wrecking cars. The road is being built and operated by Mr. Miller, aided by the following staff: General Manager, Miller A. Smith, M. Am. Soc. C. E.; Superintendent, Wm. F. Sharp; Master Mechanic, Wm. Holland; Auditor, W. Bundy Cole. The inspector for the government is Mr. L. P. Pennypacker, Assoc. M. Am. Soc. C. E.

We are indebted to Mr. Miller A. Smith for the accompanying profile of the road, and for a copy of the schedule of train service between Puerto Barrios and Gualan, 79.8 miles. There are 11 intermediate stations, with from 370 to 2,300 ft. of sidetrack at all but the last three stations. There is a mixed train daily each way. The train from Gualan leaves at 6 a. m., and reaches Puerto Barrios at 11.10 a. m.; the return train leaves at 1 p. m. and reaches Gualan at 6.10 p. m. The average rate of speed is, therefore, about 15 miles per hour. On Tuesdays a mail train leaves Puerto Barrios at 6 p. m., reaching Gualan at 11.10 p. m., and on Wednesday it leaves at 12.30 a. m., reaching Puerto Barios at 5.40 a. m. The grades are in general easy, with the exception of summit grades of about 3% near the coast, and about 1.6% towards the inland range.

The Guatemala Central Ry. is 75 miles long, with maximum grades of 3% and minimum curves of 15°. The track has 54-lb. rails, laid on wooden ties, 24 ins. c. to c., in stone and blue gravel ballast. The rails are laid with broken, suspended joints, spliced by 20-in. angle bars. The ties are partly of California redwood, 7×8 ins., 8 ft. long, and 7×7 ins., 6 ft. long; and partly of native hardwood, 6×8 and 6×7 ins., 6 ft. long. The locomotives weigh about 45 tons.

* * *

THE SUEZ CANAL TRAFFIC in 1895 was very prosperous, and the earnings amounted to $15,685,222, an increase of $859,810 over those of 1894. The total receipts were about $16,140,000, and the total expenditures about $7,500,000; the cost of widening and deepening having been $782,000. The number of vessels was 3,434, with an aggregate tonnage of 8,448,383 tons, while 95% of these vessels used the electric light to enable them to continue their passage at night. The average length of trip was 19 h. 18 min., of which 16 h. 18 min. were occupied in steaming through the canal. Of the 3,434 vessels, 1,250 had a draft of over 23 ft., and of these 228 had a draft of 24 ft. 8 ins. to 25 ft. 8 ins., the latter being the maximum draft allowed by the navigation rules.

◆

THE WATER POWER CANAL at Sault Ste. Marie, Mich., is now projected on a smaller scale, and it is said that the Lake Superior Power Co. has abandoned its plans for a 400-ft. canal in favor of a canal 250 ft. wide, the right of way for which has been nearly all acquired.

◆

A BOILER EXPLOSION occurred on June 29 at Houston, Tex., which killed three persons and injured a fourth. The main shell of the boiler, which was a small one, used in a newspaper office, is stated to have been thrown 300 ft. from the boiler house through the brick wall of the office of the Southern Pacific Ry. Co. W. G. Van Vleck, Manager of the Atlantic System, was seriously injured. The accident is supposed to have been caused by low water in the boiler.——On June 25, at Hazelton, Pa., three of a battery of six boilers exploded simultaneously. The boiler house is reported as totally destroyed and the remaining boilers were twisted and distorted. The engineer was only slightly injured.

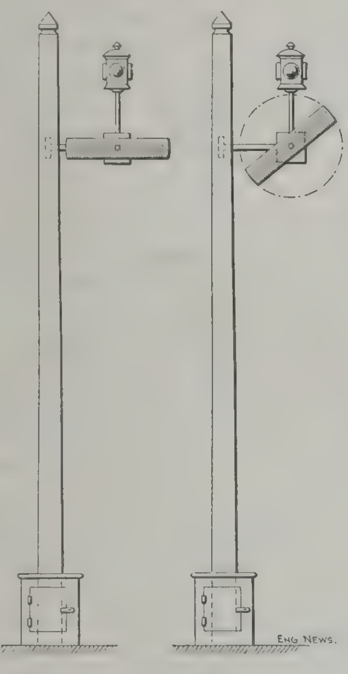
---

*The Meriden plant was described in Engineering News for July 18, 1895, and a small Woolf plant at Brewsters, N. Y., a few miles from Danbury, was described in our issue of July 13, 1893.

A REVOLVING SEMAPHORE SIGNAL.

One of the latest novelties in railway signals is the Bezer revolving signal, the principle of which is that if the signal is moving the train may move, while if the signal is stationary the train must come to a stop. The signal post carries a horizontal arm which supports a box containing the mechanism. On the front of the box is a signal arm pivoted at its center (like the semaphore blades on some of the English railways), while from the top of the box projects a spindle carrying the lamp. The mechanism is operated by electric batteries of the Gordon & Burnham make, placed in a box at the foot of the post, and which are being continually charged from a primary battery, which is in turn charged from chloride storage batteries in a well near the track. A track circuit effects the connection between the batteries of each signal, and only one line wire is required. As the train passes a signal the arm ceases to revolve, while the arm on the next signal ahead (the block being clear) begins to revolve, making about ten revolutions per minute. The lamp has four bulls-eyes, two red and two white, and forms an intermittent flashing signal. The arrangement of the gearing and mechanism is such that the arm will always stop in a horizontal position, with the lamp showing a fixed red light. Should any failure, however, cause the arm to stop in any other position and the lamp to show a white light, the signal would still indicate danger from the fact of the arm and lamp being stationary. No spectacle is required, the only glass in the signal being the bulls-eyes of the lamp.

There are three of the signals now in service on the Delaware, Lackawanna & Western R. R., near Kingsland, N. J., and they were inspected a few days ago by a party of engineers and railway men. At the drawbridge is a mechanical or manual signal, and as soon as this has been set at "track blocked" by the passage of a train, the first automatic signal, ¾-mile in advance, begins to revolve (indicating "track clear"). As the train passes this signal, the motion ceases (indicating "track blocked"), while the second signal begins to revolve. The block sections are ¾-mile long. The normal condition of the signals is at rest, fulfilling one of the cardinal principles in signaling; namely, that the signals should normally indicate danger. Any failure of the wires, batteries, connections, etc., also cause the signal to stop and indicate danger.



Bezer's Revolving Semaphore Signal.

The system is simple and inexpensive, and the signals above mentioned have been in service through the past winter. The system may be worked automatically, as above described, or may be operated from a signal tower; the inventor is in favor of having tower men at intervals, the semaphore arm working automatically in all cases. The system is claimed to have the advantage of the electric slot, without the electrical joint or connection which may introduce an element of uncertainty in an electrically slotted position signal. On a four-track road, the signals might be placed on opposite sides of the two posts, thus avoiding the expense of bracket posts, while the fact of the lamps being thus 6 ft. apart would preclude any liability to a confusion of signals. The mechanical part of each signal (as distinguished from the electrical part) is interlocked with the next signal beyond, so that in case of a failure of any signal to indicate "track blocked" no two consecutive signals will indicate "track clear." If an engineman finds a signal (1) at "track blocked" he waits the time limit or gets a clearance card and then proceeds. If he finds the next signal (2) at "track clear," however, he regards this only as a "caution" signal, as it may have failed in action, and have thereby set Nos. (1) and (3) at danger, in which case he may find a train standing at (3).

This system is the invention of Mr. Henry Bezer, Signal Engineer, of New Rochelle, N. Y., whose address for the present is at Kingsland, N. J.

DIAGRAM OF FROG AND SWITCH VALUES.

The formulas involved in frog and switch work, though not complicated in themselves, are very often a trouble to engineers and involve the expenditure of considerable time in getting at and working out the formulas for each particular case. We publish herewith a useful and practical diagram, prepared by Prof. Malverd A. Howe, of the Rose Polytechnic Institute, Terre Haute. Ind., giving at a glance the values of the various lengths, etc., for any given number of frog, and no "mathematics" are required beyond a few simple multiplications. If the frog number is not known it can be ascertained by measuring l and b and dividing the former by the latter. The results are exact enough for all practical purposes, as shown by the following comparison between the formulas given on the diagram and Parson's formulas:

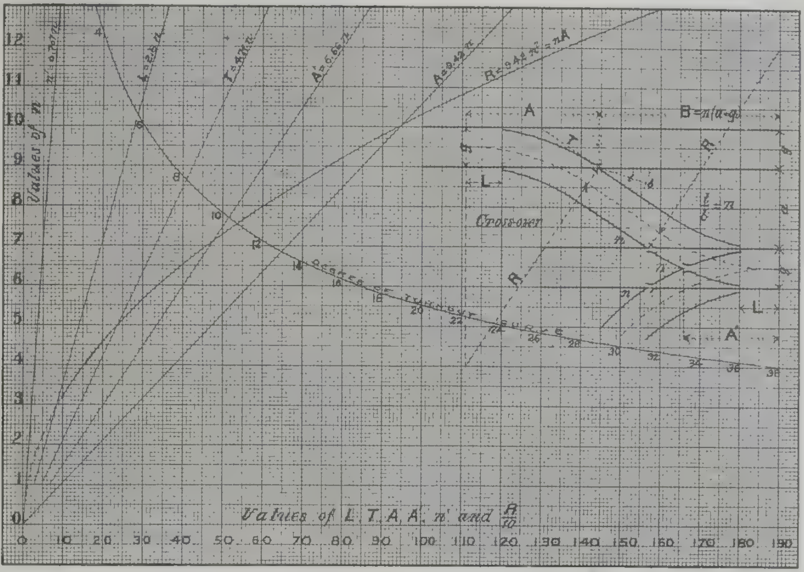


DIAGRAM OF FROG AND SWITCH VALUES.

THE ANNUAL CONVENTION OF THE AMERICAN RAILWAY MASTER MECHANICS' ASSOCIATION.

We gave on pages 420, 421 of our last issue the report of the first two days' sessions of the 29th annual convention of this association, held at Saratoga, N. Y., June 22, 23 and 24. On the concluding day of the convention the special committee on the Stevens Institute scholarships reported proposed amendments to the constitution, making these open first to the sons of members or deceased members of the association, and if there are not enough of these to fill the vacancies then the scholarships will be open to other railway employes or their sons. This amendment will be voted on next year.

On motion of Secretary Sinclair the by-laws were amended so that the meeting next year will begin on the third Tuesday in June. It has opened for some years past on the Monday following the Master Car Builders' convention.

The Apprentice Boy.

The committee on this subject was instructed to report on the best method of training apprentice boys and on what means can be adopted to improve their technical education. The committee sent out circular letters inquiring concerning the system in use for training apprentice boys, and received over 300 answers, indicating that the topic is one in which the members generally are more interested than in almost any of the mechanical subjects which are commonly considered by the association's committees. The report opened as follows:

> Your committee believe the necessity of the times change the environment of the apprentice as well as the mechanic. With the passing of the small shop with a few boys, bound under written agreements and bonds signed with legal formality, there must be a new era for the apprentice.
>
> We see with the modern corporations a breaking down of the old method of shop organization, suitable for the fathers and grandfathers, but no longer suitable for progressive organization. While in the past it may have been possible to hold a boy bound under agreements, such methods do not answer with great corporations, such as our railroads are fast becoming, extending through several states, with their aggregation of shop employees gathered from the heart of great cities, from the suburban districts, and sometimes from small villages which are almost dependent on the corporation for their existence, the bond gives way to a comity. The boy is taught fidelity and is given examples in the principles of loyalty, and the time is fast approaching when the young man will feel a loyalty to the corporation second only to the state or church. To bring about this is the duty of men handling large bodies of workmen.

Concerning the ratio of apprentices to mechanics, the replies received by the committee varied widely. On the whole the committee was of the opinion that in the ordinary railroad shop the best results are obtained by the employment of one apprentice to five able mechanics. To the question: "Have you a system of technical instruction for apprentices?" the replies showed a gratifying number of evening schools in mechanical drawing and mathematics. With most of these schools, however, no effort is made to the further advancement of the pupils after completion of the school work.

The committee then submitted schemes for the technical instruction of railway shopmen and apprentices proposed by Prof. W. F. M. Goss, of Purdue University, and Mr. I. H. Howerth, Class-Study Secretary of the University Extension Department of the University of Chicago. It also called special attention to the advantages offered by Railroad Y. M. C. associations, to the lecture study course of the University of Chicago, and to the proposed organization of the Purdue Mechanics' Institute. In the discussion President Smart, of Purdue, who was present, explained in some detail these mechanic's lecture courses which Purdue is about to organize.

Mr. Forsyth (C. B. & Q.) criticized the committee for not preparing and submitting a system of instruction for apprentices. On his motion it was voted that the subject be continued with instructions to the committee to recommend a course of shop training for machinists' apprentices or other apprentices in locomotive shops, and also to make definite recommendations for the technical education of shop apprentices.

The discussion continued for some time, bringing out among other things the value of the work being done by the correspondence schools, the fact that mathematics and drawing are of much less importance than instruction in physics, and that lectures to young apprentices cannot take the place of systematic personal instruction.

Subjects for Committee Reports in 1897.

The committee reported the following list of subjects for consideration at the convention of 1897:

1. What kind of metal should be used in locomotive cylinder valve seats and slide valves; as hard as can be worked, medium, or soft? and should the hardness of the metal for valves and seats be the same? or should one be harder than the other?
2. Which is the most economical, a planished iron boiler jacket, or a boiler jacket made of common sheet iron, or sheet steel, painted? The general appearance, first cost, and cost of maintenance to be considered.
3. For anthracite and bituminous burning engines engaged in passenger and freight service, what should be the ratio of grate area to total heating surface, and to cylinder volume? For such engines, what is the best ratio between the diameter of cylinder, and length of steam port?
4. What is the best method of securing crank pin collars used in connection with solid rods.
5. Committee to report as to whether it would be advisable and practicable to introduce piece work in connection with locomotive repairs. Also best method of arriving at prices for the different operations.
6. Have cast steel driving wheel centers any advantage over cast iron, other than the reduction in weight?
7. What classes of work in an ordinary locomotive repair shop can best be performed with air motors, and what is the relative convenience and economy of air motors for such work, as compared with motors driven by electricity, or steam? When air motors are used, should the shape of the cutting edge of drills, reamers, etc., be changed from the ordinary practice?
8. Is it desirable or economical to use extended piston rods for cylinders more than 18 ins. in diameter in the simple American type of locomotive? How should such rods be carried through the front cylinder head, and what means should be provided for supporting the weight? What provision should be made for keeping dirt and dust from this piston rod?
9. What is the best material for piston rods, iron or steel?
10. Can cast steel be used successfully for eccentric straps, and is it superior to cast iron for this purpose?
11. Best construction and material for a locomotive pilot, to be used in connection with M. C. B. coupler.
12. A revision of the air brake instruction rules. The committee to work with a similar committee appointed by the Master Car Builders' Association and to make a joint report to both associations.

Driving Box Wedges.

From the report and discussion upon this subject, it appears that practice is tending toward the disuse of the old-fashioned wedges for driving boxes, and toward the use of fixed jaws with liners between the jaws and the box to take up the wear. With narrow bearing surface, however, frequent adjustment of the liners are necessary to keep the locomotive in good condition.

Steps and Handholds.

The gist of this report was that from the investigations made by the committee, it appeared that the majority favor the placing of steps on the front corners of the tender, but not on the rear corners of the engine as well. This tender step should be a wide double step, to accord with the practice of the majority of roads. Various other standard locations for steps were proposed and finally the committee recommended that to insure comparative safety the form and location of locomotive steps and handholds should be so nearly uniform that in mounting or alighting one could, even in the dark, readily locate with his feet and hands, all the steps and handholds of any locomotive.

Miscellaneous.

The report of the committee appointed to advise the proper angle for swing-beam hangers in locomotive trucks was read by Mr. Mackenzie. On motion the committee was continued another year with instructions to have railways make experiments during the year and report results to the committee. Practically the same course was taken with the report of the committee on locomotive grates. Neither this nor the preceding paper were in type, hence discussion of them was practically impossible. The report on standard thickness for engine truck wheel flanges was then presented, and the common sense of the report so commended it to the members that the changes recommended were at once made.

The committee on standard sizes for locomotive boiler tubes then presented its report that the association's standard specification for locomotive iron boiler tubes be changed to read as follows:

> Tubes 2 ins. Outside Diameter.—.095-in. thick and weight at least 1.91 lbs. per ft.; .110-in. thick and weight at least 2.19 lbs. per ft.; .125-in. thick and weight at least 2.47 lbs. per ft.; .135-in. thick and weight at least 2.65 lbs. per ft.
>
> Tubes 2¼ ins. Outside Diameter.—.095-in. thick and weight at least 2.16 lbs. per ft.; .110-in. thick and weight at least 2.48 lbs. per ft.; .125-in. thick and weight at least 2.80 lbs. per ft.; .135-in. thick and weight at least 3.01 lbs. per ft.
>
> Under the heading of "Surface and Inspection," "And must be of uniform thickness throughout, except at the weld, where one gage number additional thickness will be allowed" be changed to read "where .015-in. additional thickness will be allowed."

These modifications in the standard specifications were adopted.

The following was presented by Mr. W. H. Lewis and adopted:

> Resolved, That it is the sense of this association that the statement of performance of locomotives should be made on the basis of ton-miles of train load in lieu of train-miles or of loaded car-miles, as is the prevailing practice at present.

Officers were then elected for the ensuing year as follows:

President, R. H. Soule; First Vice-President, Pulaski Leeds; Second Vice-President, Robert Quayle; Treasurer, O. Stewart.

Messrs. John McKenna and Alexander Galloway were elected honorary members of the association.

After discussing the place for holding the next convention an informal ballot was taken with the result that Colorado Springs had 40 votes to 24 for all other places combined.

The final adjournment was then taken.

* * *

A FLYING MACHINE is reported as being tested at Miller, Ind., by Octave Chanute, Past-Prest. Am. Soc. C. E. The machine is fastened to the body with straps, leaving the legs free, for starting, which is done by running against the wind. It is reported that a number of successful trials have been made, the machine rising to a height of 15 ft. and sailing for a distance of 200 ft.

BOOK REVIEWS.

A TREATISE ON LAND SURVEYING.—Comprising the Theory and the Practice. By William L. Gillespie, L. L. D., formerly Professor of Civil Engineering in Union College. Revised and Enlarged by Cady Staley, Ph. D., President of Case School of Applied Science. Part I., Land Surveying and Direct Leveling. New York: D. Appleton & Co. 8vo.; cloth; pp. 424 + 127; with 427 illustrations and many tables; $2.50.

We doubt not that to many of our readers Gillespie's "Land Surveying" was one of the earliest and most diligently studied of their engineering text-books, and that they feel for it still the same familiar respect and friendly prejudice that one always feels for a good text-book from which he learns the rudiments of any science and to which he often refers in after years.

We learn from the preface to this work that Part II., on Leveling and Higher Surveying, was only partly completed at the time of Prof. Gillespie's death, in 1868. This work was then taken up and completed by Prof. Staley, and was published in 1870. Seventeen years later the two parts were revised and united in one volume; but it has been found that the class of readers who desire the matter contained in Part I., have seldom use for the geodetic work, topographic work, etc., which is discussed in Part II. It has therefore been decided to again separate the parts, and the volume before us is the new and revised edition of Part I. We believe it will be received with much favor by teachers in engineering schools, and will be appreciated also as a manual for daily use by practical surveyors. The publishers deserve high praise for the mechanical work upon the volume. The type is remarkably clear; the illustrations are excellent; the tables in the last 125 pages are printed on a special paper with a rough surface and a cream tint, so that the leaves turn readily and do not show soil like the smooth calendered and dead white paper in the other part of the book. The cover of the book, however, is a green cloth, the color of which comes off when wet, and this is a serious defect in a book which will often be desired for use in the field and often will be carried in moist hands. We advise the publishers to change the style of their binding for books of this sort.

STATE RAILROAD CONTROL.—A History of Its Development in Iowa. By Frank H. Dixon, Ph. D., Assistant in Political Economy, University of Michigan. New York; Thos. Y. Crowell & Co. 8vo.; cloth; pp. 250; map and tables; $1.75.

The future development of railway regulation in this country is possible along two lines; either government ownership and government management must be adopted, or else the policy of state and national commissions must be elaborated and codified so as to make their influence practical and useful. It is not our purpose to elaborate this statement here, but its truth must be admitted unless we are to return to the old evils of private control alone. Dr. Dixon's book is a useful one to the man who realizes these facts, for it presents in a clear and concise form the history—the successes and failures—of the veritable struggles made by one of our great commonwealths in its efforts to evolve a just and efficient system for controlling the operations of the railways within its borders. Iowa is the state selected, and perhaps no more happy selection was possible. In that state trial has been made of both types of railway commissions now existing in this country, and an opportunity is had to compare their workings under nearly the same conditions. Space will permit only the author's general conclusions from this study, which are briefly: The success of a particular form of commission is dependent upon the character of the population, the industrial conditions and the geographical location, and the multiplication of state commissions is not a solution of the problem of control, but it must be worked out through a division of powers between state and national commissions.

* * *

SUBMARINE TORPEDO BOAT DESIGN is to be encouraged by the French navy department, the Minister of Marine having offered a prize of $2,000 for the best design of a submarine torpedo boat. The minimum requirements are a speed of 12 knots on the surface, with a radius of action of 100 miles; a speed of 8 knots when submerged, with a radius of action of 10 miles; two torpedoes, ready for launching, to be carried, and the total displacement not to exceed 200 tons. If there should be several good designs submitted, additional prizes of less amount may be given.

* * *

THE ARCHITECTURAL COMPETITION for plans for a block of model tenement houses in New York city, has resulted in the award of the prizes to Messrs. James E. Ware, Ernest Flagg and A. W. Ross. The competition was instituted by the New York Commission on the Improved Housing of the Poor, of which Mr. Richard Watson Gilder is the Chairman.

* * *

A TEST OF A 24-IN. submerged cast-iron water intake, at Burlington, Vt., showed it to be as tight as when accepted, about two years ago. The pipe is nearly three miles long and was laid on the bed of Lake Champlain, by Mr. J. G. Falcon, of Evanston, Ill. The intake was described in our issue of June 21, 1894. We are indebted to Mr. F. H. Crandall, Superintendent of the Water-Works of Burlington, for the above information.

A NEW SITE FOR THE 20,000,000-gallon driven well plant for Camden, N. J., has been selected at a point much nearer the city than the original location. This will save 16,000 ft. of 36-in. cast-iron pipe, for which the contractor allows $105,000, making the price for the new supply $420,000. The new location is near the present reservoir in the town of Stockton, N. J., and the land comprises 56 acres of meadow ground, triangular in shape, with a frontage of about 1,000 ft. on the New Jersey channel of the Delaware River. Work will be started at once. The contractor, Mr. Geo. Pfeiffer, Jr., has sublet parts of the work as follows: Driven wells, Kisner & Bennett, Belmar, N. J.; two 10,000,000-gallon horizontal compound pumping engines, Holly Manufacturing Co., Lockport, N. Y.; stand-pipe, Tippett & Wood, Phillipsburg, N. J. It is expected that the driven wells will be about 90 ft. deep. A bond of $200,000, guaranteeing quantity and quality of supply for ten years, has been given by the contractor.

◆

BIDS FOR LAKE TUNNELS AT CLEVELAND, O., are wanted until July 31, as stated in detail in our advertising columns. It is proposed to build a brick-lined tunnel 9 ft. in diameter and 26,000 ft. long, terminating four miles from the shore of Lake Erie. Bids are also desired for an 8½-ft. brick-lined tunnel 15,000 ft. long, extending from the present intake crib. Mr. D. E. Wright is director of public works.

◆

TESTS OF TWO 30,000,000-GALLON Holly triple expansion vertical pumping engines for the Philadelphia Water-Works were recently made by Prof. H. W. Spangler, M. Am. Soc. M. E., and Mr. D. A. Decrow, M. Am. Soc. M. E. From a report of the test sent us by Mr. John C. Trautwine, Jr., Assoc. Am. Soc. C. E., Chief of the Bureau of Water, it appears that the engines exceeded the duty guarantee of 120,000,000 ft.-lbs., one by 8.5 and the other by 4.5%.

◆

A WATER FILTRATION COMMITTEE has been appointed at Pittsburg, Pa., by the mayor, Mr. Henry P. Ford. Among the eight members are Messrs. Robt. Pitcairn, Superintendent Pittsburg Division and General Agent of the Pennsylvania Railroad Co.; E. M. Bigelow, Director Public Works; and Dr. J. Guy McCandless. The advisability of filtering the present water supply from the Allegheny River will be considered.

◆

SLOW SAND FILTRATION FOR INDIANAPOLIS has been formally adopted by the Indianapolis Water Co., and Mr. Allen Hazen, of Noyes & Hazen, Boston, has been invited to prepare the necessary plans for the construction of filter beds. This will be supplementary to the present supply from infiltration galleries, driven and deep drilled wells. Mr. T. A. Morris is president, and Mr. F. A. W. Davis is treasurer of the Indianapolis Water Co.

◆

A CHEMICAL PRECIPITATION PLANT for treating the sewage of the Wayne County poor farm buildings, near Detroit, Mich., has just been completed. The engineer for the work was Mr. Geo. Y. Wisner, Sanitary Engineer for the Detroit Board of Health. The sewage first passes through a 30-ft. mixing channel, where it receives lime and alum. It then goes through three precipitating tanks placed side by side, each 4½ × 75 ft., giving a total flow of 225 ft. The effluent falls 4 ft. over a series of steps for aeration and finally discharges through an iron pipe into a small brook leading to the River Rouge. The plant cost about $10,000. Heretofore crude sewage has been discharged into the river, but complaints were made before the court, it is said, and the practice was ordered stopped.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred June 27, on The Union Pacific, Denver & Gulf Ry., near Bierstadt, Colo. An express train consisting of engine, baggage car and two coaches ran into an engine which was taking water. Both engines were wrecked, and one engineman was killed and several persons were injured. The express was 15 minutes late.

◆

A NEW BRIDGE FELL under an electric car near Carrollton, O., July 1. The accident was caused by the derailment of the car, wreching one of the trusses of the bridge. The line on which the accident occurred is owned by the Dayton Traction Co., and was opened for traffic on the day of the accident. Two cars containing invited guests were run over the line, and as one of these entered a bridge over a canal between Alexandersville and Carrollton, the front truck left the rails and struck the side of the bridge. The car was going very slowly and, according to the account in a Dayton newspaper, the bridge broke in two at the center and sank down so gradually that no panic was caused among the passengers, and the car remained right side up, but with one end tilted down to the break at the center of the span. No one on the car was injured. From a rough newspaper sketch, we judge the bridge was a pony truss structure of wooden or composite construction.

◆

A WOODEN HIGHWAY BRIDGE COLLAPSED at Hancock, Md., June 29. A four-horse team with a load of bark was crossing it. One driver was killed and another seriously injured. The bridge was built in 1889. It had been considered dangerous, and props had been placed under it, running up from the bed of the creek.

◆

THE TIDAL WAVE which followed the earthquake in Japan on June 18 is stated to have devastated the northern shores for 170 miles; many sea coast villages were totally destroyed and several thousand people are estimated to have lost their lives.

◆

A LOCOMOTIVE BOILER EXPLODED, July 2, on the Louisville & Nashville Ry., 27 miles north of Birmingham, Ala. Three men were killed and 18 cars were wrecked. The engine is said to have been in good condition at the beginning of the trip.

◆

A RIOT was precipitated at Cleveland, O., last week by a student from one of the scientific schools, who, in company with several others, had been conducting a series of tests at the works of the Brown Hoisting & Conveying Machine Co. Upon emerging from the works he was threatened by a crowd of strikers and shot one of them in self defense. In the fight that followed between the strikers and police a number of people were injured. The strike is occasioned by the workmen's objection to the employment of non-union men.

◆

A PHOTOGRAPH OF A TORNADO has been sent us by Mr. K. E. Hilgard, M. Am. Soc. C. E., Engineer of Bridges, Northern Pacific R. R., in response to the statement made in our issue of June 11, that so far as we knew only two such photographs had ever been taken. This photograph was taken by Fredericks & Koester, of St. Paul, Minn., and shows the so-called Lake Gervais cyclone, which occurred July 13, 1890. Owing to the blackness of the sky and the faint outlines of the funnel-shaped cloud, the possibility of a successful engraving is doubtful, and we do not reproduce the photograph, but refer to it here as a matter of record in connection with the Oklahoma tornado illustrated in Engineering News of June 11.

◆

THE PASSENGER DEPOT of the Baltimore & Ohio R. R. at Wheeling, W. Va., was carried away by a flood on July 6. The depot was built at the mouth of Wheeling Creek.

◆

FATAL ACCIDENTS FROM ELECTRIC CARS in Brooklyn now number 156 since the first introduction of the trolley, according to the records of the daily newspapers. The 156th victim was killed on July 8, and on the same day two collisions occurred, one at a crossing and one a rear collision. In the latter, two persons were injured.

◆

THE TRANSMISSION OF ELECTRIC POWER has made it possible to operate, profitably, the Virginius mines of the Caroline Mining Co. at Ouray, Colo. These are situated near the summit of Mount Sneffles, in a region of perpetual snow, some 12,700 ft. above the level of the sea, or 5,000 ft. above timber line. Access to the mines in winter is impossible and in summer extremely difficult. Before the introduction of electricity in 1891, fuel, delivered at the mines, cost $18 per ton. The electric power now used is derived from water which passes through a pipe line 4,000 ft. long to Pelton water wheels driving General Electric dynamos located at the foot of the mountain. The transmission line for the electric current passes first through dense timber, then over rocks and chasms and heavy snow drifts until it reaches the mine four miles away from the power house. The current is direct and the potential 800 volts. The amount of power now used is double that supplied by the superseded steam plant, and it is estimated that the saving pays, each year, the entire cost of the plant.

◆

A MAIL TUBE is under consideration for carrying mail between the New York and Brooklyn post-offices. If built it will cross the bridge and be operated by electricity or pneumatic pressure. The bridge trustees ask a rental of $8,000 for the first two years and $6,000 a year thereafter. It is stated that the post-office department is willing to pay from $14,000 to $15,000 a year to a company that will transport the mail by tube. The plan would greatly expedite the interchange of letters between the two cities and it is to be hoped that it may be carried out.

◆

MAIL COLLECTING AND SORTING WAGONS are reported as the latest proposed improvement in the United States Postal Service. These wagons would run in outlying districts and by having the mail sorted on them and placed in separate pouches according to destination much time could be saved that is now lost in sending mail to central stations, besides the saving in time of collection. Motor wagons are talked of for this service.

◆

ACETYLENE GAS FOR CAR LIGHTING is reported as having been tried on the Eastern Railway of France. The acetylene was compressed in a tank similar to that used for the gas ordinarily used in lighting on the road in question. A special Manchester burner, with a very small slit, was used.

◆

EXPERIMENTAL HOT WATER MOTORS are to be tried on the New York and Putnam Branch of the New York Central Railway, between New York and Yonkers, it is reported. The motor was invented by Mr. W. E. Prall.

◆

A NEW STEEL PLANT is being built at North Birmingham, Ala., by the Jefferson Steel & Manufacturing Co. A 15-ton Hawkins furnace will be put in operation July 10, it is expected, and nine more of the same style and size as soon as they can be completed. Mr. F. W. Hawkins, the patentee of the furnace to be used, is superintending the construction of the plant.

◆

A NEW OIL PIPE LINE TO TIDEWATER will be completed soon by the United States Pipe Line Co. The company has been delayed by an injunction against crossing under the tracks of the Pennsylvania and Delaware, Lackawanna & Western Railway companies' tracks in New Jersey.

◆

A DISINFECTING SHIP is nearly completed at the port of New York and will be used by the health officers in charge of disinfecting and fumigating vessels arriving from infected foreign ports. By its use it is hoped to reduce the time required to disinfect a vessel to one hour. Arriving vessels will be met and passengers transferred to the quarantine ship. All their wearing apparel will be subjected to a steam bath at 230° F.; and the passengers themselves will be obliged to take antiseptic baths.

◆

FIVE NEW PIERS, capable of accommodating the largest steamships afloat, will be built on the North River water front of New York city within a year by the Dock Department. The piers will be 100 ft. wide and 675 to 730 ft. long. Two of the piers have been applied for by the Cunard line and two by the White Star line.

◆

PROPOSALS FOR ORDNANCE MATERIAL are called for by the Ordnance office of the War Department until Aug. 3. The material desired includes 18 sets of forgings for 10-in. and 12-in. guns, and one set for a 16-in. gun, which will be the largest caliber yet attempted in this country. Proposals for 30 disappearing gun carriages, for 60 sets of steel mortar forgings, for finishing and assembling them, and for spring return carriages for mounting them are also asked.

◆

THE THREE 30-KNOT TORPEDO CRUISERS authorized at the last session of Congress promise to be the subject of more competition than was expected. Besides the Herreshoff Bros. the Columbian Iron Works, of Baltimore, has announced its intention to submit bids, and it is thought that the Cramps and one or two other firms will also submit figures.

A NEW SOLID FLOOR FOR HIGHWAY BRIDGES.

Solid floors are very desirable for highway bridges, but in many cases the increased cost has prevented the adoption of such a floor. To meet the objections as to cost, and at the same time to provide sufficient strength and durability in the cheaper floor, Mr. John O. Pew, General Manager of the Youngstown Iron & Steel Roofing Co., has designed and patented the system shown in the accompanying cuts.

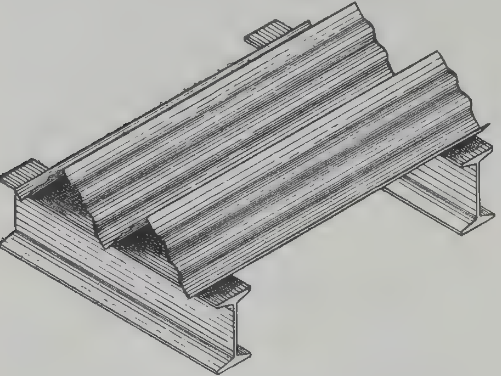

Fig. 1.—Galvanized Steel Troughs for Bridge Floor.

It consists of a series of galvanized iron troughs, 5½ ins. deep and 9¾ ins. wide, each trough having one or more corrugations along its faces to stiffen it and bind the trough more firmly to the concrete filling. The general form of the trough is shown in Fig. 1. The metal varies from No. 20 to No. 10 gage in thickness; No. 20 is for bridge sidewalks, No. 18 for country bridge roadways, and No. 16 for city bridge roadways. The metal is galvanized to protect it from corrosion. In order to get sufficient bearing on the floor beams the lower edges of the trough rest in wrought-iron or cast-iron chairs on the beams. The concrete filling is made with Portland cement concrete, and is finished off to an even surface for the paving, the concrete being 3 ins. thick over the tops of the troughs, as shown in Fig. 2.

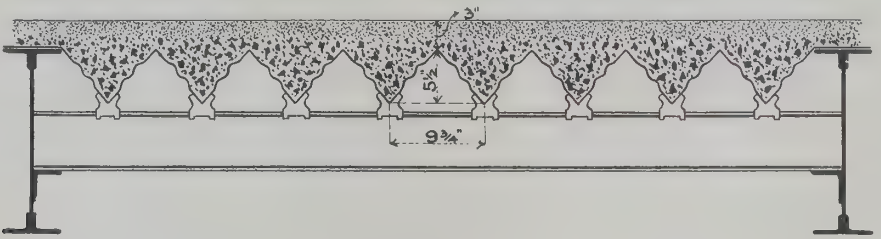

Fig. 2.—Cross Section of Solid Floor Roadway for City Bridges Showing Concrete Filling.

A section of floor having troughs of No. 18 steel, with a span of 3 ft. 10 ins., was loaded with pig iron, as shown in Fig. 3, the total load amounting to 16,534 lbs., or 1,016 lbs. per sq. ft. The load was not increased beyond this, as the pig iron could not be piled any higher. No appreciable deflection was noted, and the floor was in no way injured. This section of floor had concrete paving, 3 ins. above the tops of the troughs. Another test was made with a section of 7 ft. 10 ins. span, the troughs being of No. 16 galvanized steel, and the concrete being filled in to the tops of the troughs. This section carried without injury a load of 1,300 lbs. per sq. ft., the loading being then stopped on account of the height of the pile of pig iron.

The Youngstown Iron & Steel Roofing Co., of Youngstown, O., controls the patents, and we are informed that this floor has been adopted for heavy city bridges at several different places.

◆

ROCK RIVER AND MERRIMAC BRIDGES, CHICAGO & NORTHWESTERN RY.

(With inset.)

In its gradual work of replacing by new and heavier structures the old bridges along its lines, the Chicago & Northwestern Ry. Co. has recently completed two bridges, which for different reasons are of interest to engineers, and through the courtesy of Mr. J. E. Blunt, Chief Engineer, and Mr. W. H. Finley, Bridge Engineer of that company, we are able to present illustrations showing the essential features of these structures. The first bridge illustrated—that across Rock River, at Rockford, Ill.,—is of interest for its family history, the general characteristics of which engineers will recognize as typical of the history of many other American railway bridges. The second bridge is interesting on account of the method adopted in erecting it without disturbing traffic.

Rock River Bridge.—The first bridge built to carry the Chicago & Northwestern Ry. across the Rock River, at Rockford, Ill., was completed in 1852, a date at which iron bridges had been used in only a few isolated cases. Indeed, only five years before, in 1847, Squire Whipple, under the title of "A Work on Bridge Building," had presented the first rational discussion of the determination of stresses and proportioning of cross sections of truss members as the science is known to-day. The Howe truss had been known for twelve years and the Pratt truss for eight years, and many important combination wood and iron structures of these two types had been erected, but the era of iron bridges had hardly begun. Located in the West, far from the then existing centers of iron production and with the precedent of past experiences in favor of wooden structures, it was natural that a wooden bridge should have been erected at Rockford. It is not quite so easy to see, however, why a type of wooden structure which even at that early date was becoming obsolete, should have been chosen, for we find this first bridge to have consisted of five 116-ft. and two 106-ft. Burr truss spans with their clumsy trussing and reinforcing arches of wood.

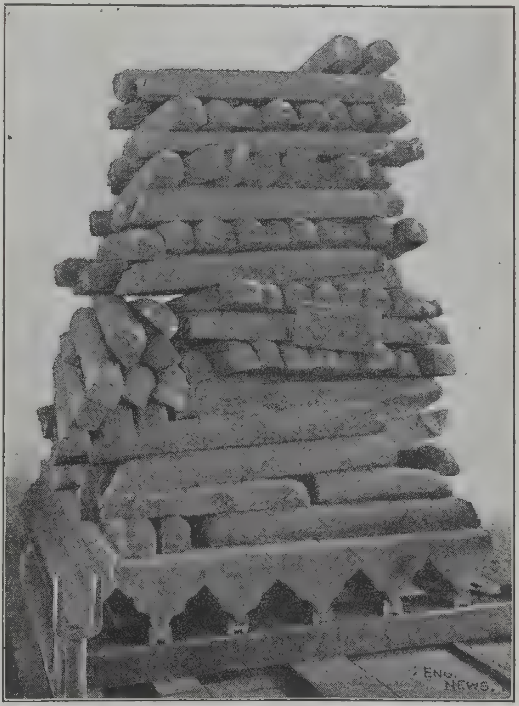

Fig. 3.—Test of Concreted Trough Floors for Bridges.

Whatever the considerations determining their selection may have been, these Burr trusses served their purpose for 17 years, when, in 1869, they were replaced by an equal number of Howe truss spans resting on the same foundations. Fig. 1, reproduced from a yellow old photograph taken in 1869, shows this work of reconstruction in progress. At the near end of the bridge is seen one of the old Burr truss spans undisturbed and just beyond is a second truss of the same type but with the arch timbers removed in the process of reconstruction. The far end of the bridge shows a number of the new Howe truss spans. This illustration will be found not uninteresting, too, on account of the single-driver inclined cylinder locomotive and the derrick car being used in the reconstruction work. It may be noted here, also, that this work was done under the immediate direction of Mr. J. E. Blunt, the present Chief Engineer of the Chicago & Northwestern Ry., who was at that time Division Engineer of the Galena Division of that railway.

The second generation of this bridge, the Howe truss, continued in use until the winter of 1895-6, or altogether 27 years, when it was replaced by the riveted triangular truss deck bridge shown by Fig. 2. This new bridge was placed on the same piers which carried the old Burr trusses of 1852, the only change necessary being the removal of the old capstones and some necessary modifications of the seats. A comparison of the old and new structures shown by Figs. 1 and 2 will suggest many things of interest to the bridge engineer, but with this brief historical introduction we proceed here to the construction of the new wrought iron structure, the grandchild of Rockford bridges. It may be noted here in reference to the use of wrought iron instead of steel that the managers of the Chicago & Northwestern Ry. Co. much prefer wrought iron to steel for bridge work, and state that up to this time they have succeeded in getting it as cheap or cheaper than steel.

The new iron bridge at Rockford is a single-track riveted truss deck bridge consisting of five 120-ft. spans and two 100-ft. spans. Fig 3 shows the general details of one of the 120-ft. spans—actually these spans are 114 ft. 3¼ ins., c. to c. of end pins—and as all shapes and dimensions are given they need not be discussed here. The manner of erecting the bridge deserves, however, brief mention, and to explain it the partial drawings of the falseworks, Fig. 4, are given.

A number of bents were constructed, as shown by the end elevation, Fig. 4. It will be noticed that the top story of this bent passes up inside of the trusses of both the old bridge (shown by dotted lines) and the new iron bridge. For each span the requisite number of these bents, generally seven or eight, were placed and then braced together longitudinally by means of horizontal and diagonal timbers held by bolts. This construction allowed the falsework to be taken to pieces and built up again quickly and easily. Enough falsework was built for three spans and after the completion of the ironwork for these spans the falsework was removed and re-erected under three other spans.

Turning now to the end elevation of the falsework shown in Fig. 4, the method of erection may be explained. After the erection of the bents and their bracing complete, the old Howe truss floor was removed and the track temporarily laid on the bents. The Howe trusses were then torn down and removed with the exception of the bottom chords, which were slid out on the first story cap of the bents and formed a track for the traveler used in erecting the ironwork. The iron trusses being erected with floor beams complete, the temporary floor on the bents was replaced by the permanent floor and track of the new bridge. All the erection was carried on without interruption to traffic. The railway company erected the falsework and tore out the old Howe trusses, Mr. R. C. Sattley, Superintendent of Bridges, Galena Division, having charge of the work. The Wisconsin Bridge & Iron Works, Milwaukee, Wis., built and erected the new iron bridge.

Merrimac Bridge.—The Merrimac Bridge crosses the Wisconsin River at Merrimac, Wis., and the work here described consisted in erecting twelve plate girder deck spans to replace the same number of riveted truss deck spans without delaying traffic, which averaged 18 trains between 7 a. m. and 6 p. m. o'clock during its prosecution. As will be seen from Fig. 5, the supports for these spans were iron towers and as the old truss spans were deeper than the new plate girder spans the towers had to be increased in height. This increased height was secured by the construction shown in Fig. 6, which also shows other details of the plate girder work, floor construction, etc.

HICAGO & NORTHWESTERN RY.

ge Engineer, Chicago & Northwestern Ry.

Lassig Bridge Works, Chicago, Ill., Contractors for Merrimac Bridge.

To erect the bridge a falsework was erected on each side of three spans, as shown by Figs. 7 and 8. This falsework was so arranged that as soon as three spans of the new structure had been completed it could be removed and set up beside three more spans. On the falsework on one side the new plate girder span was assembled complete. This being done the old span was slid sideways onto the opposite falsework and the new span put in its place. The illustrations show the method of operation in a general way, but further details are given by Mr. M. Riney, Superintendent of Bridges and Buildings, Chicago & Northwestern Ry., in a report of the work to Mr. Wm. H. Finley, Engineer of Bridges for the same company. This report was as follows:

During the erection of the twelve plate girder spans over the Wisconsin River at Merrimac, Wis., the number of trains that crossed the bridge daily between 7 a. m. and 6 p. m. was 18. Work was begun unloading the falsework the last week in September, 1895, and on Oct. 3, 4 and 5, three spans of falsework on both sides of the bridge were raised. On Oct. 5 the iron crew lowered the first girder onto the falsework, and by Oct. 7 the remaining girders and connections for all three spans had been lowered and the floor beams, laterals and stringers put in place. On Oct. 9 the first set of girders was moved onto their permanent position. To allow of this shift the running of trains was so arranged that the time between 2 p. m. and 4 p. m. o'clock was left free from trains. In making the shift the first thing done was to remove the ties from the old bridge. A block and tackle was then hitched to the old span and it was slid bodily out onto the falsework by means of a hoisting engine. The time occupied in doing this was three minutes. The hitches were then changed to the new girder span, blocking meanwhile being placed on the towers to provide for the less depth of the girder span. The new span was then slid into place in about five minutes. The old span was moved about 14 ft. and the new span about 15 ft. from their original positions. Before starting to move the new span the ties had been placed so that all that remained to be done was to put the rails into place. The procedure with the remaining spans was exactly similar and the following statement shows the time occupied in placing each new span complete:

No. span.	Hrs.	Mins.	No. span.	Hrs.	Mins.
1.	2	30	7.	1	10
2.	2	00	8.	1	30
3.	2	05	9.	1	40
4.	1	15	10.	1	30
5.	2	00	11.	1	40
6.	1	45	12.	1	30

Only one train was delayed and that during the change of the first span when the men were new to the work and over careful.

When the three new spans had been set, the next task was to remove the old spans so as to get at the falsework to move it to a new position. Two long pine timbers were placed on timber horses transversely across the car with their ends overhanging on each side of the bridge, Fig. 7. By means of block and tackle operated by a hoisting engine, also on the car, two bents of the falsework on each side of the bridge were picked up and the cars moved along the bridge to the points where the bents were to be set again. Everything possible was handled by a locomotive, hoisting engines, and a wrecking car. The first span was set in place Oct. 9, and the last Oct. 31.

The designs for both this bridge and the Rockford Bridge and also the methods of erection were the work of Mr. Wm. H. Finley, Engineer of Bridges, Chicago & Northwestern Ry. The Merrimac Bridge was built by the Lassig Bridge Works, of Chicago, Ill., and it was erected by Mr. A. B. Carson. The forces of the railway company put in the falseworks and handled them during the work.

THE SAFE THICKNESS FOR ENGINE TRUCK WHEEL FLANGES.*

Your committee is asked to report on the thickness of engine truck wheel flanges, recommending the minimum thickness at which it is safe to allow the leading truck wheels to run.

At the last convention, at Alexandria Bay, a communication was received from Mr. T. J. Hatswell, master mechanic of the Flint & Pere Marquette R. R., asking that this matter of the thickness of engine truck wheel flanges be discussed. It appears that Mr. Hatswell had had a difference of opinion with the Railroad Commissioner of the state of Michigan, arising from an accident on his line by the derailment of an engine at a frog on a perfectly straight track, which was attributed to a thin flange on the engine truck wheel. The wheel in question was steel-tired. The flange of the wheel, measuring by the gage, was 13-16-in., which Mr. Hatswell considered perfectly safe in running. The commissioners fell back on the M. C. B. rules, claiming that they recommended wheels to be condemned with a flange 1 in. in thickness, and that a steel-tired wheel ought not to be rated with a flange thinner than a cast-iron wheel.

We have made rather extended investigations, and find a considerable variance in practice. We find the allowable thickness to vary from ¾ to 1⅛-ins. in steel wheels, and from ⅞ to 1 and 3-16-ins. in cast-iron wheels, a range for which there seems to be no good reason. There is a considerable number of mechanics who follow the practice of permitting a thinner flange in steel wheels than on cast-iron wheels, and we confess that your committee started its work of investigation with a bias in favor of this practice. It seemed at first that a steel-tired flange could be worn thinner than a cast-iron flange, inasmuch as in condemning one the reasons were entirely different; that is to say, a cast-iron flange ought to be condemned when it developed wear, on account of its liability to break, whereas a steel-tired flange ought to be condemned when it showed wear, not on account of its liability to break, but on account of its liability to climb the rail through being sharp. We very shortly changed our views of this matter, however, and now think it can be demonstrated very clearly that there should be but one thickness as a minimum for a leading engine truck flange, whether the material is cast iron or steel. In support of this view, we submit tracings that show that by allowing even moderate wear to a steel flange, the life of the wheel will give out much more rapidly, owing to the quantity of tread surface that subsequently has to be turned off and thrown away, in order to produce a standard thickness of flange.

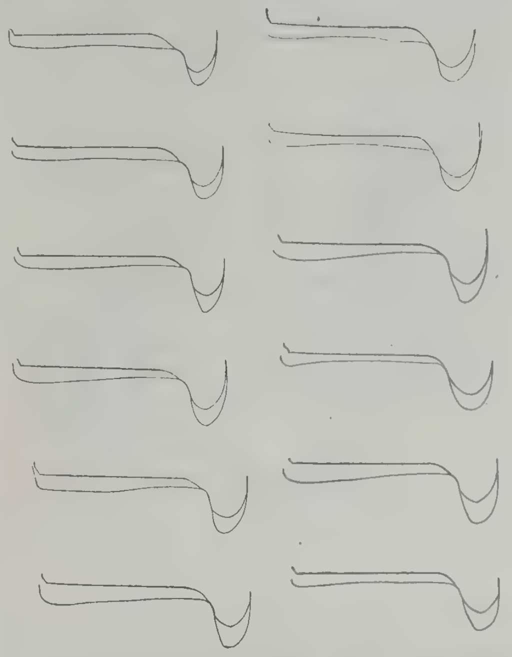

Fig. 1.—Contours of Engine Truck Wheel Tires With Flanges Worn Thin, and Standard Section after Turning, Showing Amount of Metal Required to be Removed.

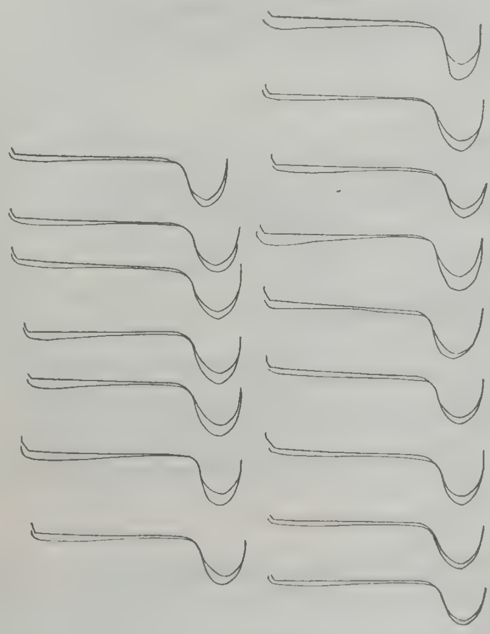

Fig. 2.—Sections Showing Economical Limit of Flange Wear on Engine Truck Wheels.

These tracings show the outlines of a number of coach tires which were taken on the C. B. & Q. Ry. several years ago by Mr. A. Forsyth, master mechanic of that road. We append a letter from Mr. Forsyth, which, with the accompanying drawings, we believe fully demonstrates the correctness of our position.

To sum up, your committee would definitely recommend:

1. That the minimum thickness of leading engine truck wheel flanges should be the same for both iron and steel wheels.

(Note.—In recommending that the steel flange limit be the same as in cast iron, the fact that the strength of steel admits, with perfect security, of a thinner flange has not been lost sight of by your committee. Our recommendation is based purely upon economical considerations as to tire wear.)

2. That the minimum thickness be 1 in., measured at a point ¾ in. from the top of flange, as shown on the appended diagram, Fig. 3.

Pulaski Leeds, G. W. Rhodes, R. M. Galbraith, A. F. Stewart and W. D. Crosman, Committee.

Appendix.

Aurora, Ill., May 18, 1896.

Mr. G. W. Rhodes, Supt. M. P., C., B. & Q. Ry., Aurora:

Dear Sir: Replying to Mr. Crosman's communication attached. Up to 1890 it was our practice on the C., B. & Q. to run steel-tired wheels as long as they could possibly run with safety. This was done with the idea that we were getting more mileage out of the steel tires by so doing. During the year 1889, I took contour lines from every steel-tired wheel that came to the shop for tire turning, and in April, 1890, the matter was brought to the attention of the C., B. & Q. Master Mechanics' Association, and blue prints of 171 tires as they arrived at the shop, and the amount of metal that had to be turned off the tread in order to make a good flange, were presented at that time.

In order to illustrate this, I have selected from these contour lines (Fig. 1), and present on the enclosed drawing twelve extreme cases which show the enormous amount of metal wasted from the tread of the steel-tired wheels by allowing the wheel to run until it has a very thin flange.

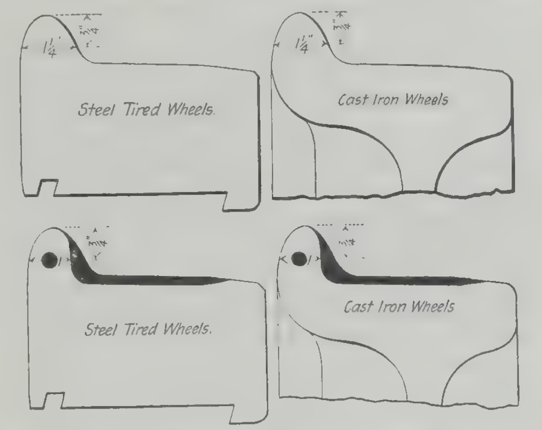

Fig. 3.—Standard Flange and Minimum Flange Thickness Recommended for Engine Truck Wheels.

On the second drawing (Fig. 2) I have shown selected contour lines of sixteen steel-tired flanges that had commenced to develop flange wear. At our Master Mechanics' meeting it was decided that it was not economical to allow flange wear on steel-tired wheels to get any worse than is shown on this drawing.

A. Forsyth, Division M. M., C., B. & Q. Ry.

THE COSTA RICA RAILWAY.

From a report by Mr. George E. Church, M. Am. Soc. C. E., one of the directors of the Costa Rica Ry. Co., of London, we take the following brief description: The line extends from Limon, on the Atlantic coast, to Alajuela, 117 miles, with a branch 20 miles long to Guapiles. The grades are from 1½ to 4%, the latter being at the summit of the range, and the curves are from 12 to 20°. There are 143 bridges, with an aggregate length of 10,702 ft., which is an indication of the great amount of waterway to be provided for floods, etc. All the bridges are of iron, with a minimum span of 20 ft., and there are 25 bridges with lengths of 129 to 620 ft. Floods and landslides cause much damage to the railway and its structures.

The line has a gage of 3 ft. 6 ins., and is laid with 50-lb. rails on the main line and 40-lb. rails on the branch. Between Limon and San Jose (the capital city) there are 99,500 wooden ties, of which 27,500 are of lignum vitae (estimated to have a life of 15 years on the Panama R. R.), the remainder being of Colombian and native hard wood, which requires renewal in a few years. All the other ties are of steel, of which 20,130 were on hand for renewals in June last. It is recommended that all renewals should be made with steel ties, except that lignum vitae should be used on the first 12 miles, as the action of the climate and the sea air is very destructive. The steel ties, after 7 years' use, show a wear of about ⅛-in., under the outer flange of the rail.

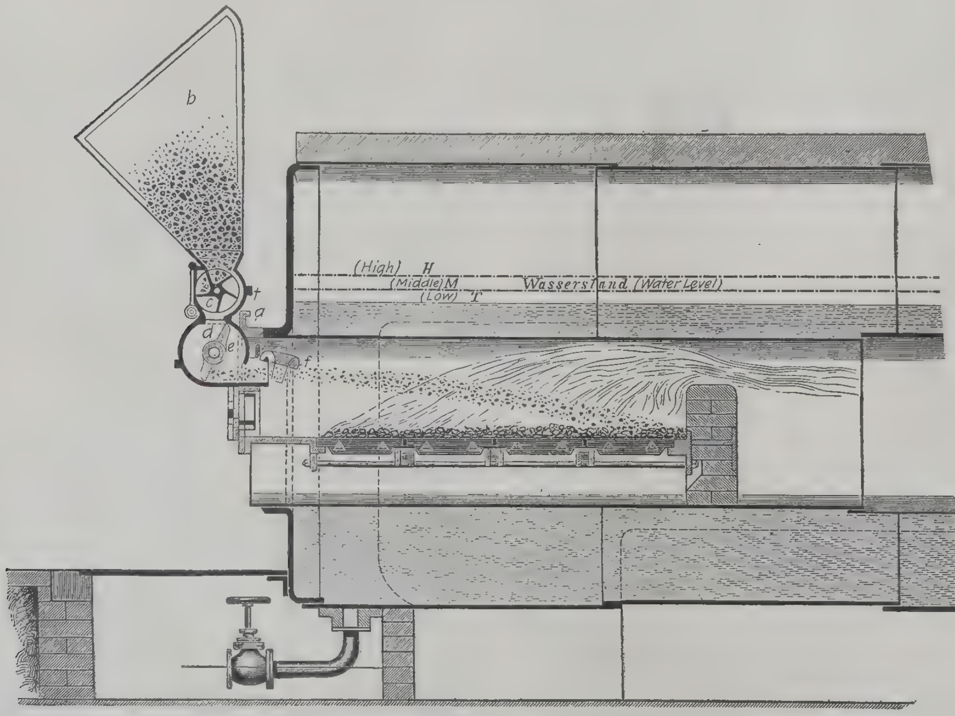
---

*A committee report presented at the annual meeting of the American Railway Master Mechanics' Association.

There are 22 locomotives, of six or seven different types, and it is considered that 16 mogul engines and 2 six-wheel switching engines could more economically handle the traffic. At present large American engines (from the Baldwin Locomotive Works) are used on the heavy divisions, hauling the same trainloads which the smaller English engines haul on the other divisions. There are 37 passenger cars, of various types, and the small English cars are considered inferior to the American cars on account of their greater proportion of dead load. The freight equipment aggregates 284 cars, and here again the American cars, with a capacity of 20 tons and over, are considered to give more economical service than the small English cars of 8 and 10 tons capacity. These latter, however, are at present preferred for certain traffic. It is recommended that all new cars should have iron or steel sills, as wood has so short a life in this climate. At Limon there is a wooden pier 930 ft. long, 50 to 70 ft. wide, along which two tracks are laid. The piles are subject to rapid destruction by the teredo navalis, and a new iron pier, at a different location, is proposed. Some particulars of the early history of this railway will be found in our issue of Feb. 16, 1889.

A GERMAN MECHANICAL STOKER.

That our readers interested in mechanical stokers may see what is being done in that line on the other side of the water, we reproduce herewith illustrations of a mechanical stoker which is being placed on the market by the "Sachsische Maschinenfabrik zu Chemnitz." We venture to say that most American engineers, after examining the accompanying drawings of the apparatus, would pronounce it an unmechanical and absurd contrivance; but, notwithstanding this, if its manufacturers tell the truth in their circular, it seems to be giving a very good account of itself in service, being in use in some 150 different establishments, many of which have from 5 to 14 boilers equipped with it.

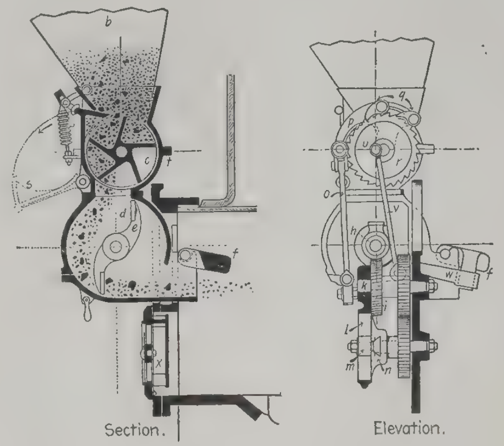


A GERMAN MECHANICAL STOKER. LONGITUDINAL SECTION OF INTERNALLY FIRED BOILER, WITH STOKER ATTACHED.

Made by "Die Saechsische Maschinenfabrik" Zu Chemnitz.

The makers state that either anthracite or bituminous coal may be used, but the kind best adapted is a nut coal, with pieces varying from ¼ to ¾ in. in size. By changing the speed of the rotating shaft, however, it is said that pieces as large as 2¼ ins. may be stoked. The feed is adjustable to suit different rates of combustion.

The general principle of the device is evident from the accompanying drawings. The coal is thrown into the furnace by wings on a rapidly revolving shaft, and is fed to that shaft in measured quantity by a slowly turning wheel at the bottom of a hopper. One would suppose that clogging and breakage of these two shafts would be too common to make the machine a success; but if that is the case how do so large a number come to be in use?



Cross Section and Front Elevation of Operating Machinery of Stoker.

It will be seen that the stoker is designed for attachment to an internally fired boiler; and it certainly is an attractive feature that none of the moving parts are directly exposed to the fire. Apparently, also, it can be attached to the front of an ordinary boiler with very little difficulty.

It will be seen that the stoker has firedoors of its own, fitted with slides; and as the doors remain closed, it is claimed that a smokeless combustion may be obtained through suitable manipulation of the slides and the chimney damper.

We leave American stoker manufacturers to decide whether this apparatus is so poor that the Germans adopt it for lack of something better (in which case the American stoker makers will do well to pay attention to their German export trade); or whether it is so excellent that it ought to be introduced in this country.

STEEP GRADES ON ELECTRIC RAILWAYS.

By S. L. Foster.

In 1892 railway men began to realize that heavier motors were needed. The forerunner of the latest series parallel controller appeared on the scene and the cost per mile was brought down to a more reasonable point. These powerful motors rendered feasible grades that it would have been unwise to operate with the old equipment. The toothed armature cores, instead of smooth cores, and the protected field spools, reduced the item of motor repairs, and a large amount of power formerly wasted at starting was saved by the new controllers. In San Francisco the unusual grades encountered led to the use of two 25 HP. motors on each single truck car.

These 25 HP. motors are far in excess of what is required to propel the cars on the level, and we thus see already that some of the penalties for operating electric cars on heavy grades are the necessity of transporting heavier motors than are needed on the level, the attendant lower average car efficiency and the increased rail joint abuse.

It is hardly necessary to note that single truck cars have been found to be better than double truck cars for heavy grade work as in the former the motors are given the benefit of all the adhesion the weight of the car can give, while in the latter some of this weight is supported by the four wheels that do not act as drivers for the car.

There is a misconception in some minds as to the power that is really required by an electric car on a grade. The formula used in determining the force required to propel a vehicle shows that when on a grade this force increases rapidly with the grade when the speed remains the same. But the speed of an electric car does not remain the same on a grade as on the level. The motors are only capable of a certain effort and as on a grade the car not only has to be advanced horizontally, but also raised vertically at the same time, the work to be done is increased and the car speed decreases until it is within the power of the motors.

Another feature of grade climbing—the freedom from wagon interference is often overlooked. On a road where heavy grades prevail very little wagon traffic is met, and the slow running and frequent stops and starts so prevalent on a level line and so wasteful of power are absent. When a car starts up a grade it has an uninterrupted run to the end and its short pieces of level track are usually clear. The result of these compensations is that the average amount of electrical energy absorbed on 1,000 car miles covering seven consecutive days on a level city line is but 50% less than the average on 1,000 car miles on a city line in which several 10 and 12% grades exist. The level line is 24,000 ft. long where there is a total rise of but 142 ft. and the other was 16,000 ft. long and comprises two hills. The line rises 186 ft. to the top of the first hill, descends 92 ft. and rises to the second hill top 143 ft. The same style of cars and motors was used in both cases.

When the new series parallel controllers came out, instructions were given to use only the series notch on heavy grades as it was more economical to run the motors in series than in multiple. Let us see what the basis of this advice was and its value. On grades over 6% about two times as much current is used and over twice the speed is attained by the car when the motors are run in multiple as when run in series. This excessive flow of current causes an increase in sparking at the brushes, sends the armatures to have the commutators turned sooner and the greater speed on the grade wears the bearings and gearings more rapidly. From the standpoint of the repair shop, the series combination is thus seen to be the cheaper.

From the standpoint of the power house engineer, too, it is better for cars to be run up hill on the series notch as the power plant can handle twice as many cars that are running on the series notch as if the cars ran on the multiple notch. The lines containing heavy grades are the bugbear of the engineer on account of the abnormal fluctuations in load due to the cars climbing the grades on the multiple notch. Where the plant is nearly loaded, this sudden occasional call for four times the normal current often results in the whole line being cut out in order to assure current for more important lines.

From the standpoint of the investor, the series notch is preferable, as when cars are run up the grades with the motor in multiple the system must be not only equipped with boilers, engines, generators and feed wire, of double the capacity that would be required if the series method of running the motors were used, but this double capacity must be running and ready at all times, as it is not a case of a load coming on at 7 a. m. and 5 p. m., but it appears at regular intervals through the day and must be provided for.

From the standpoint of the watts per car mile, or the coal pile, however, the multiple notch is found to be slightly cheaper. On grades over 6% under ordinary conditions, single truck cars equipped with two 25 HP. motors were found to require, when the motors were run in multiple, from nothing to 14% less expenditure of power than when the motors were run in series.

The current will be more when in multiple, but the time will be less than in an inverse ratio to the current or, what is the same, the speed will be more than in a direct ratio to the current. For example, on a given grade two times the current is absorbed and 2.6 times the speed is attained. Thus the power is less at the multiple notch. This saving, however, is not worthy of consideration, as it is undoubtedly more than counterbalanced by the loss at the generators, due to inefficient running at under load most of the time. This saving on a 14½% grade amounts to 1¼ K-W. hours per mile of grade run.

---

*Extract from a paper read at the first annual meeting of The California Street Railway Association.

In other words, as roads are usually built with but few and short heavy grades and the rest of the lines more nearly level, the use of the multiple notch involves a slight saving for a few moments of each trip and a waste in the form of interest of money and unnecessary coal burned for inefficient generators for the rest of the time.

On a line where a number of tests were made the saving was for 6.2%, and the waste for 93.8% of the running time. The series notch is thus seen to be the more economical. Ordinary mechanical reasoning teaches us that the amount of power required to propel a car up a grade is independent of the speed. If the speed is slow the force required is less, but the time during which it is exerted is longer. If the speed is rapid the force is greater and the time less, so that the result is the same in either case. The explanation of this disagreement between theory and the facts is found when we consider the relative car efficiencies at the two notches. The efficiency is higher at the multiple notch on a heavy grade because the work done by the motors approaches more nearly their rated capacity where their efficiency is a maximum.

This greater economy at the multiple notch held good under the conditions of the tests made, only on grades above 6%. On such a grade the power consumed is the same at the series as at the multiple combination, while on lesser grades and on the level the series is the more economical notch at which to travel a given distance. The tests were made under ordinary conditions of load and voltage. Of course, every railway manager must decide according to his local conditions which is the larger, the value of the coal saved by the use of the multiple notch, or the extra expense for repair work on armatures due to the quadrupled flow of current, plus the interest on the additional station capacity rendered necessary in order to safely handle the sudden heavy calls for current made by the hilly lines, plus the interest on the extra amount of feeder wire needed to keep up the voltage when from three to four times the current usually used on the level is called for. There is still another expense to set against the saving in coal and that is the item of lamp breakage. If feeders of sufficient size are run to the hilly portions of the line so as to hold up the voltage for the few moments during which the cars are climbing at the multiple notch, these feeders will be too large for the line the rest of the time when the cars are not climbing, and the voltage will rise and as the lamps will be running up over normal candle power most of the time, their life will be shortened considerably.

The question of requiring more cars when the series notch is used on grades in order to secure the same headway will not come up unless the line is run with no layover at the ends. On the line tested comprising 33,000 ft. of single track and having five heavy grades each way, 1½ minutes only would be lost each half trip by changing from the multiple to the series method of climbing heavy grades or three minutes to made up in 50, the time of a round trip.

It is frequently asked what the steepest grade is that can be ascended by an electric car, and the question is as often left unanswered because the questioner cannot state the exact coefficient of friction between the car wheels and the rails.

It is easier and fully as much to the point to tell of what steep grades have been climbed and to call attention to the fact that it is not a question of how steep a grade can be climbed, but how steep a one can be safely descended. In San Francisco cars are operated successfully both ways on a 14.54% grade, and on the Piedmont road in Oakland on a 14¼% grade up and down. In Seattle, Wash., on Rainier Ave., by the help of sand a single truck car climbed a 16.85% grade 300 ft. long, but in this case it is not dared to allow a car to descend without an outside check on its speed.

Some motormen have devised a method whereby they can come down heavy grades rapidly, have the brakes on fairly hard and yet not slide the wheels. This result is produced by putting the controller on the series notch while the brakes are set. The maximum braking effect has been found as the result of an elaborate series of tests made by European engineers, to be produced by applying the brake shoes at a pressure just under the skidding point. In case the wheels slide, the brake shoes should be released at once, the wheels allowed to revolve and be then gripped again. The motormen referred to have found that by the use of the motors, they can hold the car braked at that point of maximum retardation just short of skidding and can keep the car wheels free from slipping, while maintaining a higher rate of speed than is possible when not using current in conjunction with the brakes. The idea of using power while descending grades, however, is just the reverse of what all street railway men have been seeking to realize, namely, how to recover, while descending, some of the power consumed while ascending. It also seems most dangerous for motormen to get into the habit of using current while descending a grade, lest in case an emergency arise, they continue to advance the controller instead of throwing it back to "off" before reversing. When at the series notch it is impossible to reverse the motors. The controller handle must first be thrown "off." If the controller is on, it necessitates one more operation before the car can be stopped, and in an emergency the time occupied for this extra move is extremely valuable.

It can perhaps be plausibly argued that a car can be stopped more quickly by causing sliding wheels to rotate than by leaving them sliding, from a consideration of the tests mentioned above. Here it was found that the pull per ton required to tow a car with the brakes set decreased from 42 lbs. to 5 lbs. as soon as the wheels slipped. Conversely it might be claimed that if the wheels were turned when slipping the car speed would be checked. It would be a good deal cheaper, however, to make these wheels turn by slacking off the brakes than by trying to do it by using current.

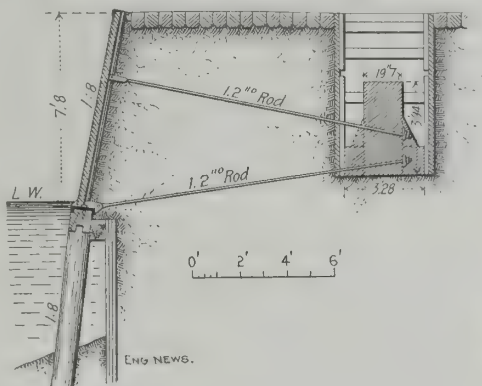


Fig. 1.—Quay Wall of Iron and Concrete on the River Spree, Berlin, Germany.

The problem of ascending grades where electricity forms only a portion of the power required for the work is solved in this locality in three typical ways—at Mt. Lowe, near Pasadena, Cal.; in San Francisco, on the Fillmore St. grade, and on Rainier Ave., in Seattle, Wash.

At Mt. Lowe two cars are permanently attached at opposite ends of a cable that passes around a winding drum in the power house at the top of the grade. The force of gravity on the descending car aids the ascending car in its ascent. The track construction is three rail with a turnout at the center of the route where the cars pass each other. The system is controlled entirely from the power house above. A positive difference in loads is made up by a stationary electric motor actuating the winder, and a negative difference is offset by a brake on this winder. Here grades as high as 68% are surmounted.

On Fillmore St., in San Francisco, we have a practical double track street railway proposition. The descending car assists the ascending car on the same principle as at Mt. Lowe. The positive difference between the loads of the two cars and the friction of the gearing, cable, etc., is made up by the use of the motors on one car; any negative difference being controlled by a band brake on the tail sheave on the hill top. When each of the two cars ends its upward or downward course, it is quickly released from the cable and proceeds on its trip. The grade here is 25.54% and about 25 HP. is used to work the whole mechanism including both cars. In this case two cars—one descending and one ascending—are essential for the working of the device.

At Seattle the line is single track, while under it is a second track in a conduit. The passenger car runs above and a load of pig iron as a counterbalance below. A descending car pulls the car of iron up to the top of the hill on to a bit of level track where it stands. The next ascending car by starting up and pulling up the cable, which is endless, starts this counterbalance car down and receives assistance from its descent in climbing the 17% grade.

Here one car only is needed at a time, but it must be always going in the right direction.

◆

A QUAY WALL OF IRON AND CONCRETE.*

The use of steel and concrete in combination is rapidly extending in this country, but German engineers are making still more bold experiments in this direction, many of which promise to be valuable improvements upon older practice. We show herewith a quay wall recently constructed along the Spree in Berlin and illustrated and described in the "Centralblatt der Bauverwaltung."

On top of a row of piles, driven into the river bed, are placed battered iron posts from 1.5 m. (5 ft.) to 2 m. (6 ft. 6 ins.) apart, to which plates of the well-known Monier construction are connected; they are from 0.6 m. (23⅝ ins.) to 1 m. (39⅜ ins.) high, and from 7.5 c. m. (2 15-16 ins.) to 6 c. m. (2⅜ ins.) thick. They are lined with cement mortar on the inside, and act as horizontal beams. The tops of the battered posts, on a level with the street surface, are braced by an angle iron, or some other light shape, and each post is anchored by two rods, one at the base and the other at a point above the center of pressure of the back filling, and slightly more than two-thirds of the height of the iron post, which gives, approximately, an equal stress upon the rods.

Two different methods of anchoring these rods are shown; in the one they pass through and are held by nuts and washers on the back of a continuous block of concrete; in the other case, which is the cheaper and easier method, an iron plate fastened to a frame of channels is used in place of the concrete.

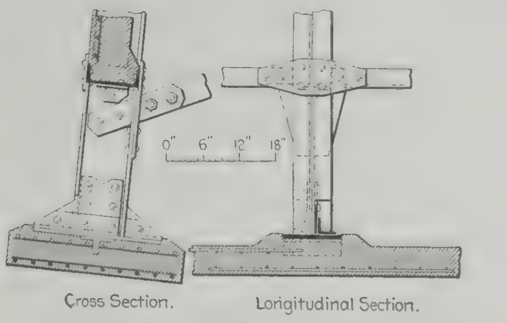

Fig. 2.—Foundation Plates for Iron and Concrete Quay Wall.

All iron that is placed under ground is protected by a coating of cement mortar 1 to 3; on the side exposed to the water the iron is cleaned and oiled.

Numerous experiments have proved that Monier plates offer a large resistance to impact; and a further advantage in this construction is the smooth and uninterrupted surface presented against the action of exterior forces. The wall at Berlin has been built as an experiment, and the observations during the last five years warrant the conclusion that it possesses a considerably greater durability than one built of wood, while its total cost per square foot of wall surface, including all incidentals, amounts to only about one-third more. These remarks apply to the construction shown in Fig. 1.

As to the expense of maintenance, actual experience is, of course, still wanting; it is well known, however, that cement offers an excellent protection to iron against rust, and that the Monier plates show satisfactory weather resisting qualities, and that, therefore, this item may be expected to be low. It is also to be assumed that the cost of future similar construction will be reduced, and the details simplified. The shore wall is perfectly tight, and proper drainage of the back-filling must, therefore, be provided.

Where it is not convenient to drive piles, a base of Monier construction, as shown in Fig. 2, and broadened out sufficiently to distribute the pressure, may be used. The baseplates retain moderate dimensions even with soil of very small compressive resistance, and are, therefore, to be especially recommended for such cases.

A mathematical investigation of the stresses in the front plate, rods and anchor plate, indicates that a considerable saving in material may be secured in carrying out similar work in future.

◆

GARBAGE DISPOSAL AT TACOMA AND SEATTLE, WASH.*

By A. McL. Hawks., Jun. Am. Soc. C. E.

Experience and Practice at Tacoma.

The population of Tacoma by the last census was 36,006, but garbage and refuse is collected from only about 15,000 people. Garbage collection is under the control of the Board of Public Works, the city's carts collecting street sweepings and the garbage and ashes being collected together by private carts. The garbage in the residence district is supposed to be collected twice a week and in the business district, and from boarding houses and hotels, daily. Ashes are removed from one to three times a week.

---

*Abstracted from the "Centralblatt der Bauverwaltung." By O. J. Marstrand, M. Am. Soc. C. E.

*Prepared from information collected by Mr. Hawks for Mr. Rudolph Hering, M. Am. Soc. C. E., and published with the consent of Mr. Hering.

The approved form of receptacle for ashes and garbage is a galvanized iron can about 2 ft. in diameter, 3 ft. high, with reinforced bottom, heavy iron rim, two strong handles and a cover. Nearly all covers disappear after a few months, as they are not fastened to the can. The cans must be placed at the curb line in the business section and on the line of the alley in the residence district of the city.

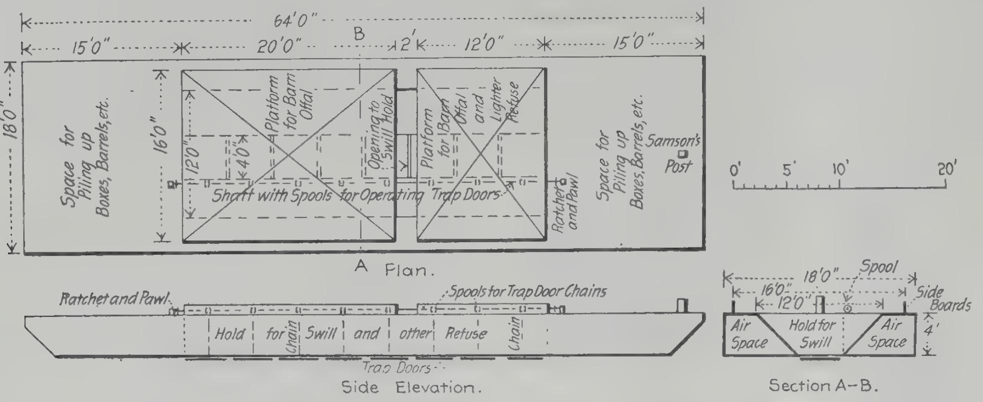

FIG. 1.—GARBAGE SCOW USED AT TACOMA, WASH., 1890 TO 1893.

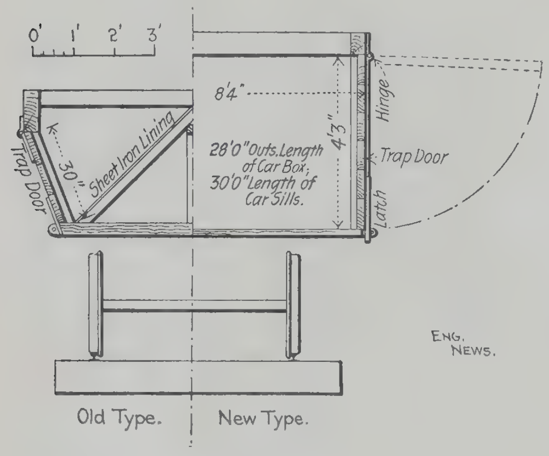

Fig. 2. Fig. 3.

Old and New Types of Garbage Cars at Tacoma, Wash.

Ordinary wagons are used for collecting garbage and ashes. Dump carts would, of course, be preferable. The garbage wagons are supposed to be water tight, with canvas covers, but such covers are not ordinarily used. They are drawn by two horses and accompanied by only one man in the residence, and by two in the business district, the hauls for these districts being respectively 1½ and ¾ miles. The wagons used cost from $75 to $125 each.

The only record of the amount of garbage, ashes and other refuse collected is for the year ending with July, 1895, the figures being taken from the books of the Northern Pacific Railroad Co., which at that time was hauling the garbage from the city. The record, in tons, is as follows:

August	295	February	250
September	290	March	230
October	330	April	240
November	320	May	90
December	310	June	156
January	360	July	108

Total for the year........................2,979 tons.

The composition of the material collected varies in winter and summer, as follows, the figures being percentages:

	Winter.	Summer.
Ashes	50	20
Barn refuse	25	50
Other material	25	30

The yearly cost of gathering the garbage may be estimated at $3,500; of hauling by train, $3,250; of spreading on land, $600; making a total of $7,350, when the garbage was shipped by rail and hauled to and spread on farm land. Disinfection of the garbage receptacles, wagons and cars is not practiced. The garbage weighs about 30 lbs. per cu. ft. in summer, dry, and 45 lbs. in winter, soaked.

The history of garbage disposal at Tacoma has been as follows:

In the summer of 1890 a garbage crematory was erected, but no information is available regarding its character and cost, further than a portion of the structure still standing, which indicates an ordinary furnace, and four fragments of bills from which the cost may be estimated as about $6,000. On Aug. 21, 1891, a contract was made for the operation of the crematory for a year at $1,051, but on Nov. 1, after several weeks of unsuccessful trial, the contract was cancelled by mutual agreement.

On Nov. 1, 1890, a contract was let for towing the garbage on a scow from the city dock about three miles out to deep water. The contract price was $550 a month for eight months, for six trips a week. The capacity of the scow was from 60 to 100 cu. yds., according to the method of loading, the weight being perhaps 1,000 lbs. per cu. yd. The contract was renewed on July 1, 1891, at $313 per month, and on July 1, 1892, for $219 per month for the same service. The latter rate continued until Sept. 15, 1893. The design of the scow is shown by Fig. 1.

After some months of scow service complaints arose that the lighter refuse and carcasses of animals lodged on the shores. The nuisances thus occasioned was mitigated through a part of the year by gray sea gulls, which from September to June followed the scow by thousands and picked up the floating matter. During the summer, however, the gull goes north, and in 1893, the complaints became so frequent and insistent that a change was made.

In September, 1893, a contract was entered into with the Northern Pacific Railroad to haul the garbage and street sweepings to Hillhurst, 16 miles distant, for $270.83 per month, or $3,250 per year. Farmers unloaded the wagons and carted the garbage about ¾ mile to their farms for fertilizing purposes. A man at $1.50 a day was stationed at the side track to unload the cars and load wagons, when at hand; at other times he sorted the material. Combustible material was thrown into one pile; tin cans, iron, etc., were thrown into another and afterwards shipped to a smelter where $7.50 a ton was paid for it; the fertilizing material was spread upon land at the rate of 36 loads, of 100 cu. ft. each, per acre the first year and 18 loads the second.

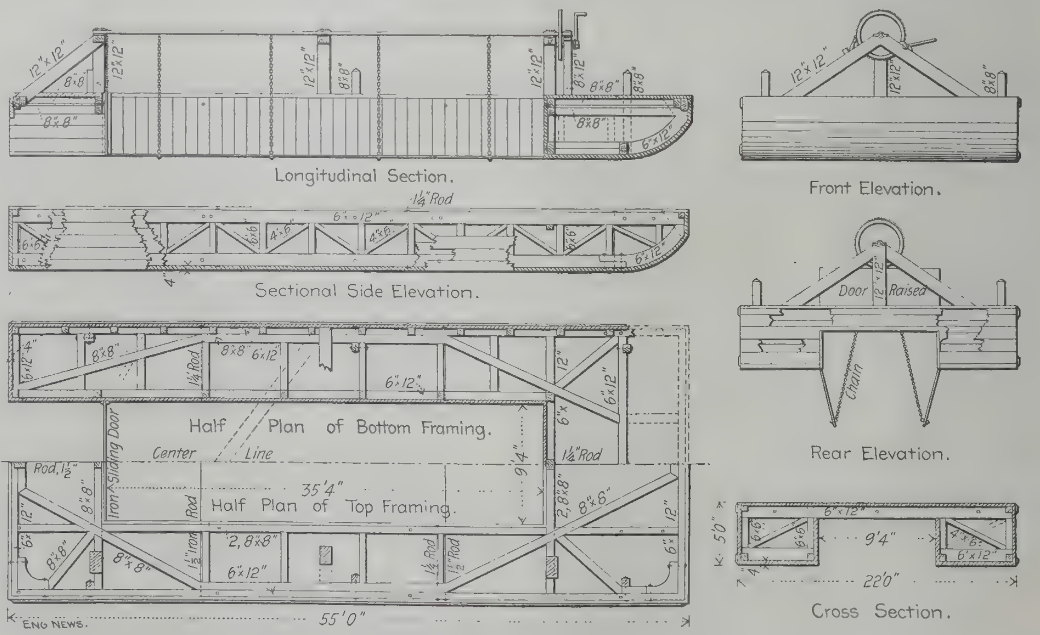

FIG. 4.—DETAILS OF GARBAGE SCOW USED AT SEATTLE, WASH.

From September, 1893, to April, 1894, the garbage was put on the farms as fast as received, the cost of cartage and spreading being 30 cts. per wagon load, excluding, and 35 cts., including, the sorters' wages. Between April and September, the farmer's busy time, the garbage was sorted and then stacked at the side track. This heap was not very offensive, no odor being perceptible at 60 to 75 yds. There was no farmhouse within ¼ mile and no complaints were made. A part of this heap was carried over to the summer of 1895, without offense. The heap would, of course, steam and give off odor if broken into.

The soil upon which the garbage was placed was a rather poor, sandy loam, which without garbage would yield about 1¼ tons of "green oat hay" or 8 to 12 bu. per acre of oats. With garbage the first year the yield was 3½ tons of hay, or 52 bu. of oats per acre. The second season was a dry one, but the yield even then was 2¾ tons of hay and 42 bu. of oats, while neighboring fields were giving but one ton of hay and 7 to 10 bu. of oats.

A comparison of the yield from 30 acres in hay and 10 in oats for two years, with and without garbage, based on the above figures, shows a gain of $474, or $237 a year, in favor of the land receiving garbage, while there would be a benefit for a few years after through an improvement in the soil. The farmers estimated that twelve loads per acre would keep the land up to the standard for the third and succeeding years, which by decreasing the cost would, of course, increase the profit.

If the use of garbage for low-priced crops shows such favorable results might it not be so profitable for market-gardening as to make it worth while for the gardeners to haul it from the city?

The garbage cars used by the Northern Pacific were of two types. Fig. 2 is a section of the older form, which was simply the common self-dumping ash car, modified a little and made larger. A few trips demonstrated that this car could not be loaded to its tonnage capacity with the light material to be carried and that the doors were too small for the easy removal of dead horses. Therefore the new type, Fig. 3, was adopted, which is simply a huge box about 7½ × 27 × 4 ft. 10 ins., inside measurement, having three doors on a side, each giving a clear opening of 4⅓ × 8¼ ft. Carcasses can be dragged from these cars by means of a horse and rope and the other matter can be discharged by means of a scraper within the car, moved by a team on the ground.

With the completion of a bridge in August, 1895, the city changed its method of refuse disposal, using the material for making a permanent roadway on the flats. At first the garbage was dumped here with the other material, taking care to keep the worst matter at the bottom. This not proving entirely satisfactory the "swill" is now taken to the "piggeries" by farmers and the remaining matter used for filling. Only one man is kept at the dump. The "hard times" has made a great reduction in garbage of all sorts, especially in "swill" from houses. Where the removal of the latter was once a source of expense to the householder, farmers will now remove it without charge, or even pay a small sum for it. In a few cases stable refuse is taken for fertilizing purposes by farmers living near the city.

Garbage Disposal at Seattle.

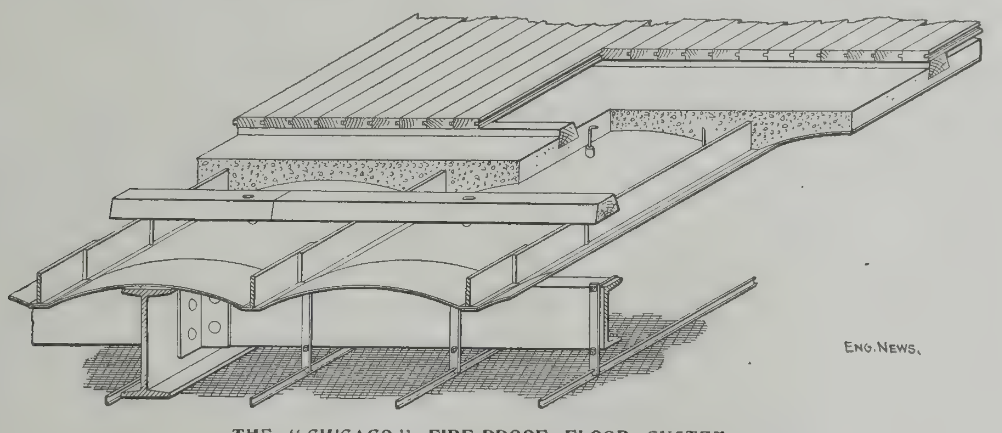
The collection of garbage at Seattle does not follow notably dissimilar lines from the system at Tacoma. Householders pay from 50 cts. per month for weekly, to $2.50 for daily, collections. The population served is about 20,000; the census of 1890 showed about 43,000 inhabitants.

Prior to 1889 no regular system of garbage and refuse disposal was in use. Since the great fire of that year these wastes have been dumped in Puget Sound, requiring a three-mile tow. The refuse is somewhat heavier than at Tacoma and is dumped in deep water, as there, but still it gives trouble along the shores.

About 15,000 tons per year are dumped in the Sound at a total cost of $97 per month, or $1,164 a year, which is about 8 cts. per cu. yd. The form of garbage scow used is shown in detail by Fig. 4.

THE "CHICAGO" FIREPROOF FLOOR.

The development of a safe and economical floor system seems to have attracted the attention of inventors to a greater extent than any other feature of fireproof building construction. Hardly a month passes that some new design is not presented to appeal for the favor of builders and architects, until now it has become a somewhat difficult task to carry in mind the different designs in actual use, to say nothing of the thousand and one which have only reached the dignity of letters patent. One of the latest floor systems which has been called to our attention is the "Chicago floor," which is the invention of Mr. Theo. Kandeler, a civil engineer of Chicago, Ill., and which is illustrated in the accompanying cut.



THE "CHICAGO" FIRE-PROOF FLOOR SYSTEM.
Theo. Kandeler, C. E., Chicago, Ill., Inventor.

The metal work of this floor consists of a series of steel bars, about 5 ft. long, and 3½ ins. wide, which are set vertically and spaced 2 ft. apart. To these bars are fastened 2×3-in. beveled wooden nailing strips, and between them are sprung sheet-iron arches, having 2½ ins. rise. This metal work complete is made in the shops in sections 5 ft. wide and 10 ft. long. In the building the sections rest on the floor beams and stringers, as shown, and are covered with concrete. The protection from beneath is secured by a suspended ceiling of fireproofing as shown.

The claims for this floor are perhaps best stated in its designer's own words, as follows:

> The safety of this floor does not depend on the quality of the concrete used, as all carrying parts, up to the floor strips, are steel, and can be proportioned with equal safety for the heaviest and for the lightest loads. If the floor strips should burn out, the concrete arch having a resistance of 50 lbs. per sq. in. would carry a load of 500 lbs. per sq. ft. All work essential to the strength of the floor is done in the factory where its quality can be perfectly controlled. The sections are opened for inspection before they are put in their places. Any amount and quality of fireproofing can be fastened above or below the floor, so that any degree of safety against fire may be obtained. The lightness of the floor follows from the exclusive use of steel for carrying purposes. The concrete is put in merely for fireproofing and deafening, therefore its quantity and weight may be reduced to a minimum. The quickness of construction is possible because all the slow work is done at the factory. This work may begin as soon as the plans of the building are far enough advanced to determine the dimensions of the floor sections, then the sections will be ready when the steel beams, which support them, are in place. The cheapness of our floor is practicable because 90% of the work in its construction is done at the factory, and factory labor is much cheaper than outside work. Another point is the lightness of our floor, which cheapens the steel I-beams, the columns and the foundations of any building in which the floor is used.

Mr. Kandeler calculates that the cost of this floor, taking into account the reduced weight of columns, I-beams, etc., will be 35½ cts. per sq. ft., as compared with 43½ cts. per sq. ft. for a tile floor.

HIGHWAY COMMISSIONS AND ASSOCIATIONS.

At the present time, when so much work is being done in road improvement and in promoting the construction of good roads, a list of the associations interested in highway work, will be of interest to many of our readers, and we therefore publish the following list, which has been kindly furnished us by Mr. M. O. Eldridge, Acting Chief of the Road Inquiry Bureau, Department of Agriculture, Washington, D. C.

Wisconsin League for Good Roads, 505 East Water St., Milwaukee, Wis.—Pres., Thomas M. Blackston, Sheboygan, Wis.; Secy., Otto Dorner, Milwaukee, Wis.; Treas., John Johnson, Milwaukee, Wis.; First Vice-Pres., Lucius Fairchild, Madison, Wis.; Second Vice-Pres., W. D. Hoard, Fort Atkinson, Wis.; Third Vice-Pres., A. Cressy Morrison, Milwaukee, Wis.; Directors, W. H. Rogers, Madison, Wis.; Wm. E. Crater, Plattville, Wis.; Thos. W Spence, Milwaukee, Wis.; C. C. Rogers, Milwaukee, Wis.; John C. Koch, Milwaukee, Wis.; A. K. Hamilton, Milwaukee, Wis.

Board of Highway Commissioners, Burlington, Vt.: Chairman, Oscar L. Hinds, Burlington, Vt.; Secy., J. W. Votey, Burlington, Vt.; Marcus Peck, Brookfield, Vt.

Ohio Road Commission: Chairman, Hon. Martin Dodge, Cleveland, O.

Connecticut Highway Commission, Hartford, Rooms 25 and 27, Capitol, Hartford, Conn.; Commissioners, James H. Macdonald, Chairman, Hartford, Conn.; A. C. Sternberg, Hartford, Conn.; Wm. R. McDonald, Hartford, Conn.

New Jersey Road Improvement Association: Prest., Clayton Conrow, Cinnaminson, N. J.; Vice-Pres., C. C. McBride, Elizabeth, N. J.; Secy. and Treas., E. G. Harrison, Asbury Park, N. J.

Iowa Road Improvement Association, Clinton, Ia.: Pres., E. H. Thayer, Clinton, Ia.; Secy., O. L. F. Brown, Des Moines, Ia.; Treas., C. B. Worthington, Des Moines, Ia.; Directors, 1st Dist., William Steyh, Burlington, Ia.; 2d Dist., Peter A. Dey, Iowa City, Ia.; 3d Dist., J. M. Muncey, Jesup, Ia.; 4th Dist., Wm. Larabee, Clermont, Ia.; 5th Dist., James Yuill, Cedar Rapids, Ia.; 6th Dist., Chas. F. Blake, Ottumwa, Ia.; 7th Dist., J. G. Barryhill, Des Moines, Ia.; 8th Dist., W. O. Mitchell, Corning, Ia.; 9th Dist., J. C. McCabe, Logan, Ia.; 10th Dist., G. L. Tremaine, Humboldt, Ia.; 11th Dist., H. C. Wheeler, Odebolt, Ia.

Virginia State Good Roads Association, Richmond, Va.; Pres., Joseph Bryan, Richmond, Va.; First Vice-Pres., Chas. E. Asburner, Brook Hill, Va.; Secy. and Treas, H. W. Anderson, "Times" Building, Richmond, Va. Vice-Presidents, 1st Dist., Orris A. Browne, Cape Charles., Va.; 2nd Dist., J. E. Booker, Suffolk, Va.; 3d Dist., B. B. Munford, Richmond, Va.; 4th Dist., Chas. T. Lassiter, Petersburg, Va.; 5th Dist., Geo. Young, Sutherlin, Va.; 6th Dist., H. A. Gillis, Roanoke, Va.; 7th Dist., H. L. Lyman, Charlottsville, Va.; 8th Dist., Geo. W. Barbour, Somerset, Va.; 9th Dist., H. C. Stuart, Elk Garden, Va.; 10th Dist., Lyman Chalkley, Staunton, Va.

Bureau of Highways, Sacramento, Cal.: Commissioners, R. C. Irvine, Marsden Manson, J. L. Maude and E. Marion Wolf (Clerk), all of Sacramento, Cal.

Massachusetts Highway Commission, 15 Court Square, Boston, Mass.: Commisioners, G. A. Perkins, Boston; Nathaniel S. Shaler, Boston; William F. McClintock, Boston; Charles Mills, Civil Engineer, Boston.

New York State League for Good Roads, Rochester, N. Y.: Pres., Gen. B. F. Tracy; Vice-Pres., W. Austin Wadsworth; Treas., S. S. Howland; Secy., John A. C. Wright, all of Rochester, N. Y.

Directors: Thomas R. Proctor, Utica, N. Y.; Hon. Wm. Cary Sanger, Albany, N. Y.; Warham Whitney, Rochester, N. Y.; J. R. Rosevelt, Hyde Park, Dutchess Co., N. Y.; Frederick Bronson, 76 Wall St., New York city; John C. Churchill, Oswego, N. Y.; Paul Tuckerman, Tuxedo, N. Y.; Arthur E. Clarke, Batavia, N. Y.; Winthrop Chandler, Barrytown, Dutchess Co., N. Y.; Chas. A. Willis, Havemeyer Building, New York city; N. G. Spaulsing, Schodack Landing, N. Y.; August T. Gillinder, 2 Nassau St., New York city; G. Howard Davison, Milbrook, N. Y.; A. Beekman Cox, Cherry Valley; Joseph C. Willits, 49 Wall St., New York city; W. A. Sweet, Syracuse, N. Y.; Dean Sage, Albany, N. Y.; Geo. P. Sawyer, Buffalo, N. Y.; John Bogart, 71 Broadway, New York city; I. B. Potter, Potter Building, New York city; Staley N. Wood, Hinsdale, N. Y.; Worthington Whitehouse, Elmsford, Westchester Co., N. Y.; Howard Willetts, 303 Pearl St., New York city; J. Y. McClintock, Rochester, N. Y.; W. Pierpont White, Utica, N. Y.; Martin I. Schenck, Greenbush, N. Y.

County Secretaries of New York League for Good Roads: (Albany Co.), Henry M. Sage, Albany; (Allegheny Co.), Capt. G. H. Blackman, Wellsville; (Broome Co.), F. M. Gilbert, Binghamton; (Cattaraugus Co.), John Sloan, Olean; (Cayuga Co.), H. V. L. Lord, Auburn; (Chautauqua Co.), Dr. W. M. Bemus, Jamestown; (Chemung Co.), George M. Robinson, Elmira; (Clinton Co.), E. C. Baker, Plattsburg; (Columbia Co.), H. R. Bryan, Hudson; (Cortland Co.), E. E. Mellon, Cortland; (Erie Co.), G. L. Williams or E. C. Sprague, Buffalo; (Fulton Co.), Geo. Fenton, Broadalbin; (Genesee Co.), Arthur E. Clark, Batavia; (Herkimer Co.), J. H. Ives, Little Falls; (Madison Co.), G. S. Tillinghart, Morrisville; (Montgomery Co.), G. S. Wagner, Fort Plain; (Niagara Co.), Eugene M. Ashley, Lockport; (Oneida Co.), T. H. Terris, Utica; Onondaga Co.), F. M. Power, Geddes; (Ontario Co.), C. C. Sackett, Canandaigua; (Orange Co.), Paul Tuckerman, Tuxedo; (Orleans Co.), Isaac Signor, Albion; (Oswego Co.), J. D. Higgins, Oswego; (Otsego Co.), F. E. Munger, Richfield Springs; (Queens Co.), F. McLachlin, Flushing; (Schenectady Co.), W. C. Vrooman, Schenectady; (Schuyler Co.), John M. Thompson, Watkins; (Steuben Co.), A. Crook, Bath; (Tompkins Co.), J. L. Mandeville, Brookton; (Wayne Co.), L. C. Cuyler, Pultneyville; (Yates Co.), John S. Sheppard, Penn Yan.

Special Legislative Committee on Good Roads, State of New York: Richard Higbie, Chairman, Babylon, N. Y.; Chas. F. Schoepflin, Gardenville, N. Y.; Eugene F. Vacheron, Ozone Park, N. Y.; Wm. W. Armstrong, Rochester, N. Y.; Henry Krenrich, Jeffersonville, N. Y.; M. F. Tobin, New York, N. Y.; Henry J. Staley, Carlisle, N. Y.; J. E. Overton, Oyster Bay, N. Y.

Special Committee on Good Roads, Nashville, Tenn.: Maj. C. A. Locke, M. Am. Soc. C. E.; Hunter MacDonald, M. Am. Soc. C. E., and W. H. Schuerman, Professor of Mathematics in Vanderbilt University; all of Nashville.

Indiana Highway Improvement Association, Indianapolis, Ind.: Pres., J. S. Mount, Shannondale, Ind.; Secy., L. B. Eubank, Indianapolis, Ind.

Missouri Road Improvement Association, Kidder, Mo.: Pres., T. O. Stanley, Sedalia, Mo.; Vice-Pres., W. C. Adams, Atherton, Mo.; Secy. and Treas., Levi K. Chubbuck, Kidder, Mo.

Good Roads Association, Cromwell, Conn.: Pres., Dr. W. B. Hallock; Secy., T. W. Beaumont; Treas., Walter Fewthrop; Executive Committee, W. S. Coe, John B. Bond, Geo. S. Butler, H. W. Congdon, and A. N. Pierson, all of Cromwell, Conn.

Darlington Road League, Darlington, Md.: Pres., D. C. Wharton Smith; Secy., C. Wilson; Treas., Alfred E. Page; W. H. H. Whitford, Chas. A. Andrew, Joshua C. Smith, Joseph R. Hopkins, Albert S. Holloway, Courtold W. Smith, W. Newlin Smith, A. Tinney Galbraith and E. M. Allen, Jr., all of Darlington, Md.

Douglas County Road Improvement Association, Omaha, Neb.: Pres., Chas. F. Manderson, Vice-Presidents, Guy C. Barton and William A. Paxton; Treas., Ben. B. Wood; Secy., Curtis C. Turner; Victor B. Caldwell; all of Omaha, Neb.

Michigan League of Good Roads: W. L. Webber, Pres., Saginaw; William Appleton, Vice-Pres., Lansing; E. M. Hopkins, Secy. and Treas., Saginaw; John McVicar, Detroit; C. V. De Land, Jackson; Silas E. Woodworth, Plainfield; H. C. Weeks, Allegan; S. S. Bailey, Grand Rapids; Dallas J. Don, Flint; G. W. Howe, Port Huron; C. H. Peters, Saginaw; Wm. Carpenter, Muskegon; William Crosby, Harbor Springs; Reuben Goodrich, Traverse City; William Chandler, Sault Ste. Marie.

Mifflin County Good Roads Association, Milroy, Pa.: Pres., Chas. Bratton, Shanks Run, Pa.; Vice-Pres., J. H. Peachey, Belleville, Pa.; Secy., S. T. Moon, Milroy, Pa.

THE NEW YORK & BROOKLYN R. R. CO. has been granted the right by the New York Board of Aldermen to build a tunnel under Ann St., from Park Row to the East River. The company proposes a tunnel under the East River terminating in Brooklyn at Middagh and Furman Sts. The length would be 8,225 ft., and approach grades of 4% as a maximum are proposed. Mr. Benjamin F. Henning, who has been prominent as an advocate of a gravity tunnel on this site, is the principal promoter of the scheme, and among others interested are Alonzo B. Cornell, E. R. Hoadley and Irving Washburn, of New York. The company has agreed to pay the city 2½% of its gross receipts. It is designed to use electricity for the motive power; but the cars will run by gravity alone down each approach and a good part of the distance across the river.

ENGINEERING NEWS
AND
AMERICAN RAILWAY JOURNAL.

Published every Thursday at Tribune Building, New York.
Entered at the Post Office, New York, as Second Class Matter.

D. McN. STAUFFER, CHARLES WHITING BAKER.......EDITORS.
WM. KENT, E. E. R. TRATMAN, M. N. BAKER, CHAS. S. HILL, A. B. GILBERT.............. ASSOCIATE EDITORS.
CHAS. W. REINHARDT....................CHIEF DRAFTSMAN.

GEO. H. FROST, F. P. BURT.............BUSINESS MANAGERS.
ALFRED E. KORNFELD, New York......; F. A. PECKHAM, Chicago................. ADVERTISING REPRESENTATIVES.

PUBLICATION OFFICE..........Tribune Building, New York.
CHICAGO OFFICE........................1636 The Monadnock.
LONDON AGENCIES: KEGAN PAUL, TRENCH, TRUEBNER & Co. (Limited), Paternoster House, Charing Cross Road; SAMPSON LOW, MARSTON & Co., (Limited), St. Dunstan's House, Fetter Lane.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the 32d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The wisdom and zeal shown by Toronto, Ont., in making the most of her franchises for the use of the public streets might well be followed by many of the cities of the United States. In our issue of Nov. 7, 1895, we published some figures showing the revenue derived from street railway franchises in that city. The Board of Control of Toronto, of which Mr. R. J. Fleming is chairman, is now advertising for sealed proposals for the

> PRIVILEGE of constructing and maintaining a telephone service for the citizens of Toronto, for a term of five years, or longer.

We have capitalized the word privilege in the above quotation. On this word hangs the whole idea of compensation to cities for valuable franchises, but most of our American cities do not appreciate the fact.

◆

In our column of "Letters to the Editor" this week, a valued correspondent directs attention to the call for competitive designs for the bridge across Newtown Creek, Long Island, and condemns in strong terms the scheme which has been adopted for securing plans for the structure. We doubt not that he voices the sentiments of many of our readers, and we ourselves were inclined on first examination of the scheme to take a very similar view. As we read the advertisement referred to more carefully, however, and consider all the circumstances in connection with the case, we find ourselves obliged to examine the matter from the point of view of those who are in responsible charge of the work, and to ask candidly whether they have not adopted a wise course on the whole in thus opening to general competition the preparation of plans for this structure.

As a matter of fact, the question of the best design for this structure has been a subject of vigorous discussion for a long time. The crossing is one of considerable length, and the conditions of traffic are such that it is desirable to obstruct the channel as little as possible. The ordinary swing-span draw will not be permitted, we believe, by the army engineers. Of the substitutes which are available, at least three or four, and probably more, are covered by patents, and we know that some at least of these patented designs have been brought to the attention of the officials in charge of this work by their owners. Moreover, there is good reason to believe that some of these patented designs are exceedingly valuable for use upon just such sites as that of the Newtown Creek bridge. It would not be wise, therefore, for the Commissioners to employ an engineer to prepare plans for the work, with instructions to use no patented devices. Neither would it be well for them to employ him to decide between various patented designs, and others not covered by patents, without first finding what royalty the owners of these various patents would ask for their use. But this is practically what the competition which has been instituted is to determine, and this, we believe, is the reason why those submitting designs are asked to place a price upon them, instead of the more common course of naming a prize which will be given to the successful competitor.

◆

In this connection a few words regarding the general conduct of competitions may be appropriate. The architects, who have had to deal with competitions ten times as much as have engineers, when they found that there was no stopping them, took the wise course of so controlling and guiding them as to secure the best results to those instituting them and those taking part in them. They formulated a system of general rules to govern architectural competitions, which has been of great value to the profession and to the public as well. One of the govering principles of this code of rules is that calls for competitions should require general designs and not details. The wisdom of this rule is easily seen. The preparation of general designs is a matter of moderate time and expense; but for detail designs a large outlay must be made. As a matter of fact the only ones who will undertake the expense of making detail designs for a competition, are the plodders of the profession who can find no more profitable occupation.

Now, as we read over the advertisement for plans for the Newtown Creek bridge, it appears to us that it conforms fairly well to this principle, as what it calls for are general designs and not detailed plans and specifications. Competitors are not even required to submit an estimate of the cost of carrying out their designs, nor specifications for use in their construction. In fact we do not see that anything is called for that is not really necessary to enable the relative merits of the competing designs to be fairly judged, nor is anything asked for that a bridge engineer could not furnish with a moderate outlay of time and expense, not out of proportion to his chances of success. Further, his compensation is not restricted to any fixed sum; but is set by himself; and if he be so ingenious and talented as to originate a design of very great merit, he is free to set a price upon it in proportion to his own estimate of its worth. This feature of the competition has the added merit, it appears to us, of guarding against the very thing which has so frequently proved an annoyance and source of complaint in competitions, viz.: the use without compensation of a design submitted in the competition. By inviting competitors to set a price upon their designs, the commissioners, it appears to us, formally acknowledge the ownership by each competitor of his designs. In the light of this acknowledgment, the use of the designs of any competitor without payment of the compensation fixed by him, at the commissioners' request, would apparently make them legally responsible to him, whether the designs were covered by patent or whether they were not.

◆

The semi-circular shield used in constructing a large sewer in Paris, France, as described on another page, is deserving of attention as being, so far as we know, the first of all large shields of this form which has been made to work successfully. In 1892 a semi-circular shield, 30 ft. 8 ins. outside diameter, was put at work on the York Road tunnel of the Baltimore Belt R. R., but it failed on account of the settling of the crown and spreading of the haunches, and had to be abandoned. The cause of this failure was the light construction of the shield in proportion to its great diameter and the heavy load of unstable clay which it had to support. Indeed, the settlement began immediately upon the removal of the falseworks centering, and before the distorting effect of the hydraulic jacks in forcing the shield ahead through the clay had come into action. The French shield illustrated is only about 19 ft. in diameter, and is working in a sandy soil of considerable stability and with but a very small superincumbent load. Despite these favorable conditions of material and load, however, the successful operation of the shield is probably due largely to its heavy and rigid construction.

A second feature of this French work which will be of interest to engineers is the operation of the shield under a very small depth of earth—less than 2 ft.—without sinking or cracking the pavement above. Indeed, its success in this respect is remarkable, and gives much encouragement for the use of the shield system in tunneling under the streets of our large cities, where the demand for underground railways, sewers and subsurface conduits of all kinds is growing each year, and where the disturbance of the street surface means always heavy expense.

◆

At the recent conventions of railway mechanical officers at Saratoga, resolutions were adopted by both the Car Builders and the Master Mechanics, protesting against the bill now pending before Congress by which the introduction of the metric system is made compulsory. These resolutions were adopted in both associations by a practically unanimous vote.

That this protest is fairly expressive of the sentiment of a large proportion of those engaged in mechanical engineering work, it would be idle to deny. It is true that many of the arguments brought forward against the metric system are as puerile as some of those presented in its favor; but there is one argument against the change whose weight it is difficult to exaggerate, and that is the expense involved in changing the present standard system of measurements. Take the one item of screw threads. The interchangeability of the present system of screw threads depends upon, first, a set of standard diameters, round iron or other metals, and second, a standard form, size and pitch for screw threads of the different systems. In almost every branch of manufacturing industry standards have been adopted for the bolts, nuts and screw threads principally used. We may mention for example the carriage industry, the standard threads for gas-pipe and fittings and the standard limit gages for round iron adopted by the M. C. B. associations. Besides screw threads, thousands of other standards of size have been adopted in the various industries and have become a most important part of the modern system of manufacturing. Would a change to the metric system mean a change in all these standards? Doubtless it would, for it would be idle to retain standards whose dimensions could not be exactly given in metric units. That many million dollars are now invested in standard gages, templates, rules, scales, etc., and in the machinery for their reproduction and use cannot be doubted; and this investment would, of course, be destroyed by a change in the system of measurements; but this, in fact, would be a trivial part of the cost of a change in the system of measurements. For a period of some 20 or 30 years it would be absolutely necessary to maintain both systems in use, or until every existing machine built according to present standards had gone out of use. Take the railway cars of the country, for example. At every repair shop it would be necessary to carry a duplicate stock of bolts, nuts, round-iron, screw-cutting tools, etc., one for cars built on the metric system, the other for cars built on the present system.

It will be evident without further illustration that the interests which would be so seriously affected by a change in our system of measurements will be heard from very forcibly, as soon as any probability appears of a compulsory adoption of the metric system.

◆

For the other arguments against the metric system, it appears to us very little can be said. The argument that the foot or the yard are intrinsically less convenient units than the meter or the centimeter is about as trivial as the claim that the meter is a better unit than the older ones because it is a ten-millionth part of the earth's quarter-circumference. The standard of length in either case is an artificial standard kept in a government depository. As for the claim that division of a unit by vulgar fractions is more convenient than decimal division, it may be said that if in certain industries this is really the case, then there is no reason why the metric units should not be divided by vulgar fractions.

Practically, however, there is little reason to believe that decimal divisions are inapplicable in machine shop work. In fact, the use of thousandths of an inch for accurate measurement is now universal in all well-managed machine shops.

It is claimed that drawings on the metric system are liable to error through misplacement of the decimal point; but it appears to us that this argument cannot be based on any familiarity with the system in use. An error which multiplies or divides the true quantity by ten is so large that it is sure to be discovered before it makes trouble. On the other hand, the metric figures being all of the same size are more easily written and more legible than the vulgar fractions of the present system. Take for instance the dimension $1\frac{13}{32}''$. By the metric system this is written 0.036. We have one less figure to write, no small figures and no need for the inch marks.

Of the advantages of the metric system in computation, and in its simplification of the whole matter of weight and measures, it is not necessary for us to speak. They must be admitted by every one who has given the system careful and unprejudiced study. The question is whether all these advantages are worth the enormous sum which it would cost to make an entire revolution in our system of weights and measures. The people on whom the burden of cost of such a change would fall most heavily can be relied upon to answer this question in the negative; and as they are pretty certain to make a very strong showing on their side when the matter comes up for final action and to secure the ear of Congress, we are not likely to see the compulsory adoption of the metric system in this country at present.

The advocates of the metric system have frequently referred to the small amount of friction and expense that was caused by the change to the metric system in Continental Europe. It must be remembered, however, that when this change was made, manufacturing industry on the modern system was in its infancy. The system of standards, and the interdependence of manufactures was then almost unknown. The opponents of the metric system have good ground for asking, therefore, that the burden which the mere making of the change will impose upon the manufacturers of the country shall be carefully weighed before a change is compelled.

SAFETY IN LOCOMOTIVE BOILER CONSTRUCTION.

In our issue of June 18 we called attention to a published statement of the New York Railroad Commission to the effect that explosions of locomotive boilers of the radial stay type had been more violent than the explosions of similar boilers of the crown-bar type. As a result of our note the Master Mechanics' Association took up the matter at its recent meeting in Saratoga, and put itself on record as certifying to the safety of the radial stay type of boiler. No evidence was brought forward, in a discussion lasting more than an hour, tending to show that the radial stay boiler is not as safe in every respect as the crown-bar; and it was found that the New York Railroad Commission had based its recent remarks concerning radial stay boilers entirely upon experience with boilers of the Wooten pattern.

It is fortunate that the Master Mechanics' Association has taken this matter up and placed itself on record so promptly in support of the radial stay boiler as good and safe construction, else we might have had the New York Railroad Commission's deliverance on this subject quoted as authority in every boiler explosion case for years to come, and it might even have had a tendency toward keeping in use the crown-bar boiler on some roads which still cling to it.

But the discussion in the Master Mechanics' Association should be of value not only as an offset to the opinion rendered by the New York Railroad Commission. Many of the facts brought out in the discussion are not as generally known or not as generally realized as they should be, and some of these it is our purpose to note.

In the first place the essential feature of difference between the two types of boilers may be briefly explained. In the crown-bar boiler the downward pressure upon the roof or crown of the fire-box is carried by rows of crown-bars extending across the top of the fire-box from side to side and supported by the side sheets at the ends. A modern locomotive may have a crown-sheet area of 30 to 40 sq. ft., and with a steam pressure of 200 lbs. per sq. in. this means a total pressure of 86,000 to 115,000 lbs., tending to force the fire-box down and out of the boiler. In the crown-bar boiler this strain is resisted partly by the sling-stays which lead from the roof of the boiler to the crown-bars, partly by the stiffness of the stay-bolts which connect the side-sheets, and partly by the mud ring which connects the fire-box to the boiler proper at the base. What proportion of the total strain will be carried by each one of these three members is, of course, impossible to say; but neither the mud ring nor the side stays are designed to carry the strain which is brought up on them by the downward pressure on the crown-sheet.

In the radial stay boiler, on the other hand, the downward pressure on the crown-sheet is carried by stays which reach across to the roof of the outer shell, and thus the opposing pressure on these two surfaces are equalized.

An advantage of great importance in bringing the radial stay boiler into use is the greater facility with which it is cleaned. With modern boilers of high pressure the crown-bars and stays must be set so closely together that it is very difficult to clean the surface of the sheet. Under these circumstances the accumulation of scale on the sheet and consequent burning is more likely to occur. The obstruction to circulation due to the presence of the crown-bars is also an added objection to their use.

All these facts have long been known and as a result the past 30 years has seen a steady change in locomotive boiler practice. The crown-bar boiler, which was in practically universal use during the early decades of the railway era, has steadily been displaced until to-day probably 90% of all new locomotives are built with radial stay boilers. The experience related in the course of the discussion at the Master Mechanics' Association is good proof that this change has been a wise one. Many instances were given where locomotive boilers of the crown-bar type had exploded from low water, with the result that the fire-boxes were blown entirely out of the boiler. On the other hand, numerous cases were given of the failure of radial stay boilers from low water in which one or more rows of the stays merely pulled through the sheet, letting water and steam enough escape through the apertures thus formed to lower the pressure and put out the fire, and this with little or no injury to the engine, crew or the trains, and very little damage to the boiler.

It is impossible to reach any other conclusion from the testimony presented before the Master Mechanics' Association than that the radial stay boiler is safer than the crown-bar.

There are some features in the design of radial stay boilers to which attention was called in the course of the discussion that deserve especial emphasis. The first is the effect of making an arched or curved crown to the fire-box instead of a flat crown, the latter of course being always used with the crown-bar boilers. If low water occurs with a flat crown fire-box, the entire crown is overheated and softened until it comes down. If low water occurs with an arched fire-box crown, the central row of stay-bolts and a narrow portion of the sheet adjoining it is first heated. Ordinarily this causes the stay-bolts to pull through and this permits the steam and water to escape through the central row of stay-bolt holes, relieving the pressure and preventing an explosion.

But the pulling through of the bolts is more likely to occur if the stays are simply screwed in the sheet, like the side stays, than if they are given a buttonhead, like the stays used with crown-bars. Recent practice is tending toward the use of the buttonhead on radial stays and it is doubtful whether the change is an improvement. It was stated in the course of the discussion that when the Denver & Rio Grande R. R. was first opened, the locomotives had radial stay boilers, and notwithstanding the fact that the enginemen were a reckless set, and burned crown-sheets were common, an explosion was unknown. So confident did the men become that no serious mishap would follow an overheated crown sheet, that one man declared his intention of burning his engine on purpose; did it, and escaped without injury. At a later date the practice was introduced on that road of using buttonheads on the radial stays, and after that some explosions occurred. The safest construction for radial stay boilers, therefore, would appear to be to make the crown with considerable arch and make the central row or perhaps the central three rows of stay bolts without buttonheads. With this construction low water in the boiler should be reasonably certain to result in no serious damage.

The two most common causes of locomotive boiler explosions are broken stay bolts and low water. The former can be guarded against by a thorough system of inspection, in connection with the use of hollow stay bolts, which automatically give warning of breakage. It may be noted also that a crown supported by radial stays is less likely to come down in case of the forcing in of a side sheet than a crown supported by crown-bars, which has its support taken away if the side sheet fails.

The occurrence of low water can be guarded against to some extent by discipline, training and selection of enginemen, but with all care some accidents of this sort are bound to happen. It is, therefore, the duty of those entrusted with the design of boilers to adopt such precautions as shall insure against serious results from low water when it occurs. We have outlined above what the best practice at present appears to be. With this construction, supplemented perhaps by a proper system of fusible plugs in the crown-sheet, a railway officer in charge of motive power may feel reasonably safe against serious disasters due to low water in his locomotives.

LETTERS TO THE EDITOR.

Power Required to Move Balanced Valves.

Sir: Your issue of June 25, page 421, top of middle column, says that "the balanced valve requires on the average twice as much work to move it as the plain valve." Of course you will at once see that our report has been misquoted, as the converse was presented in the report, viz., the plain valve took about twice as much work as the balanced. We think this should be corrected. Very truly,

G. R. Henderson,
Chairman Committee on Slide Valves.
210 Ninth Ave., S. W., Roanoke, Va., July 1, 1896.

(We make the correction with pleasure. The error was so evident that it probably deceived no one.—Ed.)

Result of Employing an Incompetent City Engineer.

Sir: I have read with much interest the letter under the caption of "Know It All Engineer," in your issue of May 28. To further illustrate the "penny wise and pound foolish" policy pursued by many small municipalities in this state and elsewhere, I have only to cite a case which has come under my personal observation. A city not so far away has a population well on to 9,000 people; the city engineer is appointed for a term of years, at the handsome compensation of $50 per month; just think of it, $50 a month for a reliable civil engineer. This most worthy gentleman has caused to be placed on one of the principal thoroughfares a large quantity of broken stone called macadam, which would just about pass through a four-inch ring. This was dumped out and scattered upon the surface of the old street; the main street, at this writing, is "muddier," the mud and filth is deeper than in the old roads which lead up to the town. If I mistake not, $20,000 per annum is allowed by the city council for street improvements. As I understand the city does not even boast of a map, such a thing as a street profile is unknown, "hit or miss" is the motto. Any reputable engineer would be glad to accept one-fourth of the money now thrown away, as compensation. The day is not far distant when the "wise men" will be compelled to step down and out, and new brains and business ability take their places.

Until this is done many more dollars will be "ditched" and the salary of the city engineer remain at $600 per annum.
Observer.
Charlottesville, Va.

◆

The Competition for the Newtown Creek Bridge-

Sir: In your issue of July 2, I notice an advertisement from the joint committee of the city of Brooklyn and Queens county, N. Y., requesting bridge engineers to submit plans, strain sheets, etc., for a bridge to replace the present Vernon Ave. bridge. This advertisement is, by its terms and requirements, an insult to the engineering profession. It would seem that there should be engineers of ability in such work in and near Brooklyn from whom one could be selected whose reputation would assure satisfactory results, without trying to secure 15 or 20 separate designs from which some inexperienced man can construct a new bridge and thus benefit by the suggestions of those who have spent time and money in acquiring the necessary knowledge and practice for such work. It is different with contractors who compete for work. They do not spend days and weeks in elaborate calculations and careful work before submitting a proposition, but an engineer must make a complete study of his problem, must prepare elaborate plans and specificotions, receive bids from contractors, in order to submit a correct figure for the estimate of cost, and must finally remember that all his work may be thrown away or used without compensation to him to assist a cheaper man to make a reputation. The only privilege that is accorded by this advertisement to a self-respecting engineer is to refrain from encouraging such proceedings by joining in the competition. Yours very truly,

James Ritchie, M. Am. Soc. C. E.
625 Hickox Building, Cleveland, O., July 4, 1896.

(We have commented on this matter in our editorial columns.—Ed.)

Securing Responsible Bidders on Contract Work.

Sir: You have frequently called attention to the fact that large amounts of money are saved to cities by advertising the letting of their contracts in your paper. This I do not deny, but I also affirm that you have done and are doing contractors a certain amount of harm, from the fact, not of the extensive advertising, but of calling together a lot of irresponsible, inexperienced bidders who slaughter prices and trust to luck or swindling to come out on their contracts. This could be remedied by suggestions to the numerous city officials with whom you come in contact that large deposits should be required to accompany bids, at least 10% of the bids, for instance. Take the city of Syracuse, N. Y., for example. At their letting in June, 1895, they required $6,000 on a bid in the neighborhood of $20,000, this to be retained till the completion of the work. The result was that they got responsible bidders and the work was finished satisfactorily. Take, on the other hand, Stony City, Ia. They require a check of $75, any foreman can bid, and trust to luck, either by selling out to the next highest bidder, or scamping on his work or beating his bondsmen to come out whole. I grant that the city will probably have to pay more when it requires a high deposit; but on the other hand the chances of litigation are less, and the chances for getting a decent job better. Might I suggest that as you have now educated municipalities up to the required point, that you now take our side of the question and see if you cannot give them a few ideas as to the desirability of having responsible contractors do their work, and that to attain this result, that they require a cash deposit amounting to at least 10% of the bid, and preferably 25%. Respectfully,

Fred. W. Abbot,
M. Am. Soc. C. E., Assoc. M. I. C. E.
620 Chestnut St., St. Louis, Mo., May 26, 1896.

(Our correspondent's letter is an excellent presentation of the evils due to careless or incompetence in the drawing of contracts, and invitations to submit proposals, and we hope it may be carefully studied by every one of our readers who has responsibility or influence in connection with this work. We regret that the publicity given to contract letting by advertising in our columns, should, in some cases, draw irresponsible competitors to bid against reliable firms; but the remedy, as our correspondent says, is not by avoiding publicity in contract lettings but by adopting the usual well-known measures to ensure responsibility in the bidders.

The officials of almost every city of any size know very well that the cash or certified check as an evidence of good faith is an absolute necessity in inviting bids; but in many small towns this necessity is not understood. Moreover, it is not obscure people alone who are uninformed on this matter. It will be remembered that in the advertisements for the last government loan no deposit was required on the part of the bidders.

What percentage the amount of the deposit should be of the cost of the work, is a question which, it seems to us, ought properly to be considered separately in connection with each important piece of work. In works involving much doubt and difficulty, a higher percentage should be required than in the case of work whose cost can be accurately estimated in advance. Enough should be exacted in any case to ensure that only responsible and competent contractors will enter bids, for it is a waste of time to attempt to do business with men who are irresponsible and incompetent. But, on the other hand, no greater deposit should be asked of bidders than is necessary to ensure bona fide and desirable bids, for everything in excess of this interposes a needless burden on every contractor taking part in the competition, and one which may be especially annoying and vexatious where decision upon the proposals is postponed for some time.—Ed.)

Some Recent Tests of Louisville Cement.

Sir: The inspection and testing of cements as carried on for commercial purposes presents some entirely different features from similar work performed in a scientific laboratory or technical school, where experiments are made to determine the exact nature of different brands of cement with a view to establishing correct estimates to assist the practical engineer in drawing up specifications for such material. The conditions under which such work is done are as different as the ends attained. In the former case the inspector has to determine whether certain material furnished from the mills under ordinary running conditions comes up to requirements laid down by the engineer under whom he is acting, in the latter the scientist pursues investigations on isolated samples of the material the results of which, valuable as they are in themselves, are useless to the engineer as affording testimony of the value of the product turned out by the manufacturer in quantity at any particular time. In short, it is the province of the scientist to lay down rules for the guidance of engineers, and, what is more important, to establish a uniform system of testing applicable to all practical cases. Such can only be done by conducting experiments over a long period and under different conditions, and with all the different brands of material that come under the engineer's notice. The inspector is to be governed by such specifications in selecting the cement as are required by his clients. While such information, valuable to engineers and manufacturers alike, can be obtained by the work of the inspector, there is so little uniformity in the manner of testing as carried on by different men that no accepted standards can be selected from their discordant results and it is difficult to institute comparisons for this reason. In well organized laboratories for research, however, more uniform results can be obtained, as usually such experiments are carried on with care, and standard methods are employed in the testing.

Particularly noticeable is the absence of uniformity in the methods used in testing what are known as the natural cements. This is mainly due to the varying nature of the material, which allows the inspector more latitude in the selection of methods applicable to any particular case. Portland cement, on the other hand, is more uniform in quality and the testing can be conducted under conditions approaching more closely to standard methods. Portland cement, being the product of two ingredients, chalk and argillaceous clay, mixed in definite proportions, carefully selected and calcined with a degree of uniformity impossible with the natural rock, necessarily is more uniform in quality. The rock from which the natural cement is made varies so much quantitatively in the proportions of its ingredients that it is difficult to calcine it all to the same extent, for even the rock from the same quarry will show such wide variations in its composition that the resulting cement will vary widely in strength. It is therefore very important that we should have uniform methods of testing which will apply to the natural cements, and while much standardizing has been effected for the testing of Portland cement it seems to the writer that much of it is inapplicable to the systematic testing of the natural material. Unlike all other kinds of testing of materials for constructive purposes, in which tests taken under different conditions can be made comparable by deductions gathered from experience, or, as is more often the case, by mathematical analysis, the testing of cement depends so much on small details overlooked by some, and too much importance attached to them by others, that this kind of testing offers but little room at present for reducing results arrived at by different men to a common standard of comparison. For instance, from some tentatives pursued by the writer, the following details in the process of testing affect to a large degree the results, many of which are not considered in the reports of tests which from time to time are published:

1. The time the cement has been allowed to stand after being manufactured before gaging.
2. The manner of gaging, whether it has been accomplished by hand or machine.
3. The filling of the mold, whether the sample has been struck off on one or both sides.

A prolific cause for the rejection of natural cement is free or unslacked lime in the material which manifests its presence by checking the briquette, thereby reducing the effective area of the cross section and causing a reduction of the tensile strength. It is the opinion of many that in moderate amounts the CaO does not materially impair the value of the cement, especially if the cement be allowed to stand some time before using, thus giving the lime a chance to air slack. If the cement, hot from the buhrs, be gaged immediately, it would be rejected as incompetent if it showed the slightest signs of checking, while if allowed to stand it would pass inspection and be classed as good material. Thus much cement is rejected by the hasty inspector which would be passed by others. If the cement be used for plastering or work of that kind it is imperative that it shall contain no trace of uncombined lime. It is therefore quite important that the time elapsing between manufacture and gaging should be specifically stated in reports of tests. This will only apply to tests on neat briquettes, for unless the lime be present in very large quantities it will not show its presence in the usual manner in briquettes mixed up with sand. It is the writer's opinion that from this cause tests on natural cement made with sand briquettes are unreliable, for it is impossible to discriminate between inherent bad qualities in the cement and apparent lack of strength caused by the lime which in time would slack out and leave a reliable article.

Referring to No. 2. In laboratories where much testing is carried on, it is found necessary to use machines for mixing, as by the aid of such it is possible to perform four or five times as much work in a given time as could be accomplished by hand. The results, however, obtained are not the same. In the first place it is not easy to adjust the amount of water correctly for mixing with the machine, while with the hand sufficient can be added to bring the mass to the proper consistency. Even with different samples of the same cement the requisite amount necessary to enable the proper consistency to be reached will vary with the time the cement has been allowed to stand after manufacture. While the machine has the great advantage of rapidity, more accurate work can be done by the hand of an experienced person. The foregoing relates to tests made with neat samples, as machine made briquettes of sand and cement are entirely unsatisfactory, for the two components do not become thoroughly mixed in the machine on account of their difference in density. For commercial testing on a large scale machine mixers are almost a necessity, due to their increased rapidity, but for accurate scientific tests the spatula, handled by an experienced man, is by far the more reliable. In fact for comparative tests machine mixed samples are not at all trustworthy, and the element of the personal equation, incident to work performed by hand, introduces less variation into the results than the many defects of the different machines at present in use.

Referring to No. 3. The effect of this detail in testing is not as large as in the two preceding cases, but nevertheless it may give rise to errors which will seriously vitiate the results. The briquette made by striking off on one side only is decidedly inferior to that which has been turned and smoothed off on both sides.

In the first case the mold is laid on a glass plate or slab of some non-porous material, filled with the mixture by pressing with a former, smoothed over the top with a spatula and then allowed to set. Even with more than ordinary care the mold is often not completely filled by this method, as air bubbles will become caught at the bottom and further pressing will cause the air to enter the cement as there is no way by which it can escape. Thus one side of the briquette will be porous and a low tensile strength will be the result caused by eccentric loading on the specimen. By turning the briquette over, however, and applying the spatula to the other side, adding a little more cement if necessary to fill out the mold, a uniform density of cross section is ensured, which in some tests made by the writer made a difference of 3.7% on a series of samples. As these tests were made with more than ordinary care a larger discrepancy can be looked for under usual conditions of working. The following table gives the results of some tests made by the writer on several brands of Louisville cement during the past year:

No.	No. of tests.	Av'ge, lbs. per sq. in.	Remarks.
1.	4,997	121.7	24 hrs. in air and 6 days in water.
2.	210	120.0	24 hrs. in air and 5 days in water.
3.	40	124.1	24 hrs. in air and 4 days in water.
4.	58	118.0	24 hrs. in air and 3 days in water.
5.	113	116.7	24 hrs. in air and 2 days in water.
6.	840	117.2	24 hrs. in air and 6 days in water.
7.	3,471	68.2	½ hr. in air and 24 hrs. in water.
8.	271	72.0	½ hr. in air and 24 hrs. in water.

It will be seen from the table that the larger number of tests were made of seven days duration. The manner of testing employed for Nos. 1, 2, 3, 4, 5, 8, was as follows: Samples were taken from the mill as the cement was packed, one sample to every two barrels. This was continued throughout the whole year from time to time so that the resulting average is a fair criterion of the product throughout the year. The cement was allowed to stand 24 hours after manufacture before gaging. The gaging was done by hand, and the briquettes were struck off on one side only, a pressure such that a man could apply directly being used to force the material into the mold. The form of mold used was that adopted by the Am. Soc. C. E., which was laid on a glass plate during the filling. The briquettes were placed in still water until broken, which was done on a hand machine.

A glance at numbers one and six shows that a higher result was obtained from hand made briquettes than from those made by machine, number one being the hand-made samples, and number six the machine made. While the number of tests is not the same, they were so well distributed that comparison is quite justifiable. The same can be seen in numbers seven and eight, the latter 271 tests, mixed by hand, showing a higher breaking strength than the 3,471 tests of number seven, which were machine mixed. Except for the different method of mixing, numbers six and seven were treated the same as all the others; 87% to 94% of the cement would pass through a sieve having 2,500 meshes to the sq. in.

Robert S. Ball.

Louisville, Ky., May 29, 1896.

Railway Yards and Terminals.

Sir: Your issue of June 18 contains a very interesting article on "Railway Yards and Terminals," by Mr. W. L. Derr. This subject is an important one and one that the text books on railway construction treat with extreme brevity.

The inadequacy of railway yards and terminals, for which Mr. Derr says the engineer is to some extent to blame, is due to a variety of causes. On all our older roads the volume of traffic has increased so many fold as to far exceed the most roseate imaginations of the original builders. Moreover, many projectors of railways are merely financiers or promoters, who can see only so many miles of main track from terminus to terminus, and fancy when they have constructed that much, with an occasional passing track, they have finished a railway. And in many cases the building of such a skeleton of a railway has exhausted all the available funds and the construction of suitable yards is a financial impossibility, even when their necessity is recognized. If the engineer of a single track railway 72 miles long should tell his employer that it would be necessary to build 48 miles of yard and side tracks, he would probably be considered an unsafe adviser, to say the least. But such a ratio of main track to sidings is not imaginary.

No typical plan will answer equally well for division points and terminal yards; the local conditions and the necessities of each case must be considered and a plan worked out to meet them as nearly as the limitations imposed will allow. A former chief used to say to me: "Go and see the division superintendents; find out what they are doing and how they do it; what they would like to do and how they would like to do it; then find out what must be done and the best way to do it; then make your yard plan."

The guiding principles laid down by Mr. Derr are well put. The capacity of any yard should not be gaged by the number of cars that can stand on its tracks, but by the number of cars that can be put through it in a given time. Yet, in a great many localities it becomes necessary to hold cars for various reasons, and the importance of providing sufficient "hold" tracks, so that the efficient working of the yard may not be interfered with, must not be overlooked. On an old established road the amount of space to be reserved for storage of "hold" cars can readily be estimated. The proper points for storage of empties should be well considered, and plenty of track room should be provided at the various points selected for this purpose. It often happens that the road has some long gravel pit tracks that can be utilized for storage of empties. Probably a large number of these empties can be profitably stored quite close to some large car shops, so that they might be put in thorough repair during the dull season and thus be ready to render efficient service when the rush season comes on. The empty car storage tracks on Mr. Derr's diagram are very long stub tracks, which are objectionable. As a rule, all yard tracks should have switches at both ends, and if in any case it appears necessary to use a one-ended track, such track should be no longer than sufficient to hold as many cars as the ordinary switching engine can readily handle. When a long stub-end track gets full of empties, the cars at the stub end are likely to remain for weeks and months, serving as bumping-posts, and no matter how long the track may be, there will always be a car run off the end of the track or broken on the bumping-post.

Mr. Derr's axiom that "all general movements of the traffic should be forward ones," has good sense behind it. Another principle, which he does not enunciate in words, but which he has indicated in his typical plan, is that at any division or terminal yard where the amount of traffic or switching (classification) is considerable, there should be two yards; that is, one for eastbound and one for westbound traffic. For instance, take a division terminal having one yard of twelve tracks, the yard may be overcrowded and the work delayed. Probably the congestion would be relieved if the same amount of track were properly arranged in two yards of six tracks each, rather than as one yard of twelve tracks. The movement of a "slow freight" over its division is expedited by having its train made up in station order. This can best be done by re-classification in a local order yard, subordinate to the classification yard, such as is indicated in the typical plan on page 396 in your issue of June 18. But if the yard has not proper facilities for such a re-classification, there will probably be a net gain in time and expenses if the trains are sent out as originally made up. Perfect classification in the rush season should not be attempted in a yard that was not designed for such work.

The "bad order" or "cripple" cars should have tracks especially provided for them, where repairs can be made promptly and economically. These tracks should be two-ended, so that cars can be taken out as soon as repaired without waiting for every car on the track to be repaired. The repair tracks should be located adjacent to the division storehouse and blacksmith shop. Some officers want to locate the repair tracks close to the reception or classification tracks, so that it may not be necessary to move a "cripple" but a short distance. But a bad order car that has been hauled five or 25 miles over the main line in a train, can be safely moved another half mile in a yard if necessary, and it is cheaper to move these cripples to the tracks near the storehouse by means of a switch engine than to have the car-repair crew spend their time "toting" heavy castings from the storehouse to distant repair tracks. It is customary to locate the storehouse and blacksmith shop adjacent to the roundhouse, and wherever it is best to locate these buildings, there should the repair tracks be.

It is said with good reason that the cars and their contents receive more damage in going through an ordinary yard than by passing over a division 200 miles long. The common method of "tail-end" switching, without having a rider on every cut, is responsible for a great deal of this damage to rolling stock and freight. Some object to poling and gravity yards because such a large number of men are required for riders, but there should be a rider for every cut, whether the tail-end or poling method is employed, and it will often be found a good business proposition to take some of the car repairers and put them on as riders. It is cheaper to employ men enough to avoid the necessity of repairing cars than to keep a large repair force and a heavy stock of car material at every yard. Again, the capacity of a locomotive in "drilling" cars can be increased or diminished according as the number of men employed with it is increased or diminished. In a properly planned yard, when a large increase of business occurs, instead of putting a second drill engine in service, the crew of riders should be doubled, and when business drops off again the same engine can still be kept busy, if the number of riders is decreased.

As noted by Mr. Derr, that very important car, the caboose, is also the source of considerable trouble in the yard. Each caboose has its particular crew. It is their temporary home; their storm clothes and dinner pails are in it. The conductor has there his desk, and the amount of clerical and literary work required of a conductor makes it necessary that he should have a desk or an office. The caboose is frequently the sleeping room of the train crew, hence as soon as possible after reaching the end of a division, the caboose should be set where it will not have to be disturbed until required for another train. The freight cars on arrival at a division point go forward in the same direction as they entered the yard. The locomotive and the caboose, after a rest of greater or less time, return from whence they came, and with the rule "first in first out," the oldest caboose should be at the front. The unique caboose track shown in Mr. Derr's diagram accomplishes the end in view very neatly. The cabooses are transferred from the eastbound to the westbound yard and arranged in order of their priority by one movement.

The scheme outlined in Mr. Derr's sketch has so many conveniences and good features that one really believes him when he says that it "does not represent any actual yard." I wonder if the plan has ever been drawn to scale. I have not attempted to do so, but I fancy it would require a piece of ground 2½ miles long and ¼ mile wide, to begin with. The sketch is an excellent arrangement, however; but railways do not as yet build their yards that way.

Mr. Derr says that the angle of the ladder track and the yard tracks should be the same as the frog angle. This view is held by many, but I do not consider it an axiom. On the contrary, there are advantages in using an angle greater than the frog angle. One is that a less length of land is required for the yard, and another is that the switches can be placed closer together. Where one switchman has to handle a dozen switches on one ladder track with a lively poling engine behind him, every foot of distance between the switches counts. If each switch is placed as close up to the preceding frog as possible, that establishes the minimum distance between switches, which is a function of the frog angle. Then the proper angle of the ladder track depends upon the distance between the parallel tracks and the distance between the switches on the ladder. As stated by Mr. Derr, the switching in a classification yard can be expedited by having switches operated from a tower by a simple set of levers without interlocking.

Mr. Derr describes a slip switch in a ladder track. There are some cases, where space is valuable, that slip switches are necessary and convenient. I have not found them necessary on a ladder track and would avoid their use wherever possible. They are hard to work and are the cause of many derailments and much profanity. The switchmen, with some reason, call them "puzzle switches." I would add to Mr. Derr's list of general principles the following: All yard switches should be point, or split, and not stub switches. Tracks in a classification yard should be not over 12 ft. c. to c., and repair tracks not less than 20 ft. c. to c.

In regard to switching passenger trains: At terminals all through trains have to be made up in reverse order after arrival and many of the cars have to be turned end for end. If a "Y," or balloon-shaped loop is provided it will prove a great convenience for such trains. Many of the "palace cars" are too long to be turned on the ordinary turntable.

The reason why so many badly arranged yards remain in service is often easy to guess. The superintendent may be alive to the fact that the work at a yard is unnecessarily expensive. The actual cost per day or per car is a matter of figures and can readily be demonstrated. A plan for reconstructing the yard may be prepared after careful study and the superintendent may feel confident that the reconstructed yard will enable him to make a great reduction in expenses. The cost of the proposed construction can be closely estimated, but it is not so easy to demonstrate by actual figures what the saving of expense will be, and the manager perhaps dreads the confusion which will reign during the period of reconstruction. The engineer who plans the rebuilding of a yard should use a bold hand and spare not. Such cases generally require radical treatment. The existing yards are generally the result of long-continued gradual growth of business and a persistent though short-sighted attempt to keep down expenses, as pointed out in the editorial on this subject in your issue of June 18.

It is unprofitable to attempt to operate a railway with old-fashioned light locomotives. It would be better to throw them away and buy new ones. The manufacturer whose shop is full of tools that were good 20 years ago will be distanced by his wide-awake competitor who buys the latest improved machinery. The railway company that continues to use old, badly planned or outgrown terminal yards will not be able to reduce its operating expenses to the figures shown by its more wide-awake competitor.

Obtaining the True Meridian by an Observation of the Sun.

Sir: I was much pleased to learn by the letters in your issue of May 14 that the method of obtaining a true meridian by a single observation of the sun was coming into use again. The observation is so easily made, the reduction of the formulae so simple, and the result so accurate and precise, that it should be universally understood and generally used in all sections of the country, and, as it requires nothing to be added to an ordinary complete surveyor's transit, except a little piece of red glass it should become very popular. In order to popularize it, however, it should be put in such shape and so carefully explained that all surveyors can apply it readily and confidently as to the result. It is with that end in view that I beg to trespass on your space by giving some practical hints as to the requisites for and manner of making the observation, and the solution of the spherical triangle, and show the degree of precision obtainable with an ordinary engineer's and surveyor's transit with a vertical arc, or preferably a full vertical circle, reading to single minutes.

I shall not attempt any demonstration of the theory as that is fully explained in all books on surveying under the topic of the Solar Attachment. All that the surveyor needs to supply himself with, in adddition to his ordinary outfit, is: (1) A piece of red glass cut or broken to a size sufficient to place in the cap of the eyepiece of his instrument and cover the aperture, so that he may look directly at the sun. (2) A table of mean refractions. All the later books on surveying contain this table; but if his book doesn't, the following will supply his wants near enough for all practical purposes, and can be copied in his field book:

Altitude.	Refraction.
17°	3′
20°	2′30″
25°	2′
40°	1′
60°	0′30″

(3) A table of declinations of the sun.

All nautical instrument dealers keep the nautical almanac for sale at a cost of 25 cts. The tables of declinations, etc., in these books are copied directly from the American Ephemeris or Nautical almanac, published at Washington for each year, some years in advance, and are based on the meridian of Greenwich. The "World Almanac" for 1896, on p. 38, contains a table of declinations for every day in the year, based on the meridian of Washington. This is a very convenient table, as it is all on one page and can be cut out and pasted in the field book. The "World Almanac" costs 25 cts.

The "Farmers' Almanac" also contains it, calculated for the 75th meridian, and so does the "New England Almanac," calculated for the meridian of New London. These two cost 5 cts. each if they have to be purchased. This is all the surveyor needs in the way of equipment.*

He should know his latitude to the nearest minute and his longitude approximately; then he is prepared to take his observation.

The simplest formula that I have seen is the following:

$$\text{Sin } \tfrac{1}{2} A = \sqrt{\frac{\text{Sin }(S-L) \text{ sin }(S-h)}{\text{Cos } L \text{ cos } h}}$$

$$S = \frac{L + h + p}{2}$$

In which A = the azimuth of the sun, or its angle with the true meridian.

L = the latitude of the place of observation.

h = the altitude of the sun, or the vertical angle diminished by the refraction.

p = the sun's polar distance = 90° + the sun's declination when it is south, and 90° — the declination when it is north.

Being desirous of knowing how closely a meridian could be obtained by this method, I established a true meridian at Perth Amboy in the ordinary way, and made my observations from the south end of that.

The latitude of Perth Amboy, N. J., is 40°30′ north, longitude, 74°16′ west.

On Feb. 1, 1895, I took a series of three observations as follows:

1st. Time, 9 h. 40 min. a. m., vertical ang. 22°28′, azm. 140°18′.

2d. Time, 9 h. 42 min. a. m., vertical ang., 22°48′, azm. 140°56′.

3d. Time, 9 h. 44 min. a. m., vertical ang. 23°07′, azm. 141°32′.

The three work out exactly.

As an illustration of the application of the formula I will work out the third.

The vertical angle reduced for refraction = 23°07′—2′ = 23°05′ = the sun's altitude at time of observation.

By the nautical almanac the sun's apparent declination for apparent noon at Greenwich on Feb. 1, 1895, was S, 17° 5′ 1.3″, which reduced to the longitude at Perth Amboy, or the 75° meridian, was the declination at 7 a. m., or 5 hours earlier; the difference for one hour was 42.76″; the time of observation, 9 h. 44 min. a. m., was 2¾ hours later than 7 a. m., making a difference of about 118″, called 2 minutes. As the sun is coming north, and its declination decreasing, the 2 minutes is subtracted and the declination becomes S 517° 3′; p., the polar distance, is 90°+17°3′ = 107°3′; then, by the formula:

$$\begin{array}{rl} L = & 40^\circ\ 30' \\ h = & 23^\circ\ 05' \\ p = & 107^\circ\ 03' \\ \hline & 170^\circ\ 38' \div 2 = 85^\circ\ 19' = S \end{array}$$

$$S - L = 85^\circ\ 19' - 40^\circ\ 30' = 44^\circ\ 49', \text{ and } S - h = 85^\circ\ 19' - 23^\circ\ 05' = 62^\circ\ 14'.$$

Then the formula becomes:

$$\text{Sin } \tfrac{1}{2} A = \sqrt{\frac{\text{Sin } 44^\circ\ 49' \times \text{Sin } 62^\circ\ 14'}{\text{Cos } 40^\circ\ 30' \times \text{cos } 23^\circ\ 05'}} =$$

$$\begin{array}{r} \text{Sin } 44^\circ\ 49' = 9.848091 \\ \text{“ } 62^\circ\ 14' = 9.946871 \\ 10 - \text{cos } 40^\circ\ 30' = 0.118954 \\ 10 - \text{cos } 23^\circ\ 05' = 0.036243 \\ 2\overline{)\ 19.950159} \\ 9.975079 = \text{Sin of } \tfrac{1}{2} A \\ \tfrac{1}{2} A = 70^\circ\ 46' \\ A = 141^\circ\ 32' \end{array}$$

As that agrees exactly with the azimuth as read on the instrument, it shows that the degree of precision is all that can be desired. By reducing the vertical angles of 1 and 2 each by 2′ for refraction and using the same declination they will each check out in the same manner. Here is another, taken when the declination is north: July 10, 1895, time 4 h. 8 min. p. m., vert. angle 36°, azm. 90° 20′. Vertical angle reduced for refraction =36°—1′= 35° 59′. Declination as above for July 10, at 7 a. m. =22° 15′ 10.6″. North, hourly change 18.93″ × 9 hours =170″, call it 3′. As the sun is going south the declination becomes N 22° 12′, and the polar distance 90°— 22° 12′=67° 48′—this will work out all right.

For a time calculation the formula is

$$\text{Sin } T = \frac{\text{Sin } A \text{ Sin } Z}{\text{cos } d}$$

in which

T=Solar time.

A=Azimuth of the sun as determined by calculation.

Z=Sun's zenith distance=90°—corrected altitude.

d=Sun's declination.

Using the example worked out above, we have A= 141°32″; Z = 90°—23°05′ = 66°55′; and d = 17°03′; then the formula becomes

$$\text{Sin } T = \frac{\text{Sin } 141^\circ\ 32' \times \text{Sin } 66^\circ\ 55'}{\text{cos } 17^\circ\ 03'}$$

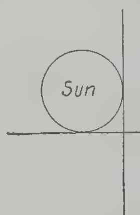
$$\begin{array}{r} \text{Sin } 141^\circ\ 32'' = 9.793832 \\ \text{“ } 66^\circ\ 55' = 9.963757 \\ 10 - \text{cos } 17^\circ\ 03 = 0.019520 \\ \hline \text{Sin } T = 19.777109 \therefore T = 36^\circ 46' \end{array}$$

in terms of angle from the meridian; 36°46′=36.75° × 4 for one degree = 147 minutes of time = 2 hrs. 47 minutes before noon by the sun; 12 m. — 2 hrs. 47 mins. = 9 h. 33 min., solar time. Equation of time for Feb. 1, 1895= 13 mins. 48.41 sec. slow, call it 14 minutes. Local time then for Perth Amboy, Long. 74° 16′ W., at the moment of observation, was 9 h. 47 mins. a. m., corrected for standard time 75th Mer. = 9 h. 44 mins. a. m. = time noted.

Now as to the practical part of the business: The surveyor can carry the little piece of red glass in his pocketbook and have it with him all the time without inconvenience, so that he may be always prepared for an observation. If he has his tables of refraction and declination pasted in his note-book and a pocket-book of logarithms with him he can work it out then and there; or he need simply note the day and hour and the two angles and work it out when he requires it, at any time.

Suppose one is running out a large tract of land for the purpose of laying it out, etc.; he selects one of the lines running nearly north and south and from the south end he takes the altitude and azimuth of the sun. The difference between his observed and his calculated azimuth is the true bearing of his line, and he has all his lines referred to the true meridian, and that part of the field work can all be done in five minutes.

As to the manner of making the observation: It is better not to try to bisect the sun. The better way is this: Get the sun in the position shown in this diagram, in which the vertical and horizontal lines represent the cross wires of the telescope. If before noon, take the lower and receding, and if in the afternoon the lower and preceding limb, and then add 16′ to each angle. The sun's diameter is 32′. This varies slightly, but not enough to affect the result for our purposes. If an instrument with a vertical arc is used it is necessary that it should be in perfect adjustment as a level or the observer won't get his altitude correctly. By using an instrument with a vertical circle he can then eliminate all errors of adjustment by this method: First, take the lower and preceding limb of the sun and read the angles; then reverse the telescope and take the upper and following limbs, and read as before. The mean of the angles will be the true vertical angle and azimuth without reduction to a centre, and all errors of colimation will be corrected. This last was the method formerly used by Mr. Geo. H. Blakeley, C. E., of the Passaic Rolling Mills when he was engaged in surveying some 15 years ago, and to him I am indebted for it.



It is fully agreed that the best time for making an observation is when the sun is moving rapidly in altitude, never near noon, or when the sun is low in the horizon. For that reason the little table of refractions given above covers sufficient range. For that reason, also, a vertical or diagonal eye piece is not a necessity, as the observation can always be taken at a time when the observer can look at the sun directly without inconvenience.

In practice it is advisable to use a line of reference and turn from that. In that case, when the red glass is used, it will be necessary to set on the line, then unscrew the eye piece cap, put in the glass and turn on the sun; with the red glass in the eye piece one cannot see anything much less bright than the sun.

If it is desired to let the sun shine through the telescope and quarter its image on a card held back of the eye piece, as mentioned by Mr. McCullough and Mr. Guinn, in your issue of May 14, and get the sun's position in that way, it will be necessary to pull the eye piece out to its full length in order that the cross-hairs may be reflected on the card, otherwise they won't appear. I mention this because I believe the fact is not generally known.

The method is an excellent one but it requires two men to do it, while the direct observation requires the observer only.

I said I was glad that this method of getting the meridian was coming in again. It was used years ago and for some unaccountable reason fell into disuse. I have before me now a copy of "Gibson's Surveying," newly arranged, etc., by James Ryan, published in New York in 1821, wherein on pp. 355 to 357 full directions are given "to find the variation of the compass by an amplitude," with examples worked out, and in Jackson's "Military Surveying," I recollect there was such a formula, with examples.

In conclusion, I beg to state that this is written for the men who are not familiar with this method of getting a meridian, but who might use it if they understood its application. Should it meet the eye of any such and they choose to work out the observations, I would suggest that having worked them out as they are, that they change the altitude and then the latitude a minute or so and then make the calculation and note the result. By that means they will see with what degree of care these factors should be determined. Very truly yours, C. C. Hommann.

Perth Amboy, N. J., May 25. 1896.

◆

THE PRICE OF GAS IN ST. LOUIS has been reduced by the Laclede and Carondelet companies to 80 cts., net, per 1,000 ft., for fuel, and $1,10 for illuminating gas, with 10% off for prompt payment in the latter case.

A HYDRAULIC SHIELD FOR SHALLOW TUNNELS.

A hydraulic shield, designed especially for tunneling under city streets at small depths beneath the surface has been in successful operation for some months in constructing a large outlet sewer in Paris, France, according to our French contemporary "Le Genie Civil." Besides its ability to work successfully with only from 1 to 2 ft. of earth above it, this shield is of interest on account of its semi-circular shape. The only other semicircular shield of large dimensions which we now recall was the one tried on the York Road tunnel of the Baltimore Belt R. R. (Eng. News, Jan. 9, 1892), and, as will be recalled, it failed to withstand the pressure of the soft clay and had to be abandoned. The cause of this failure, and the reasons for the success of the shield illustrated, are discussed more at length in another column, and here attention will be turned at once to the description of the Paris work.

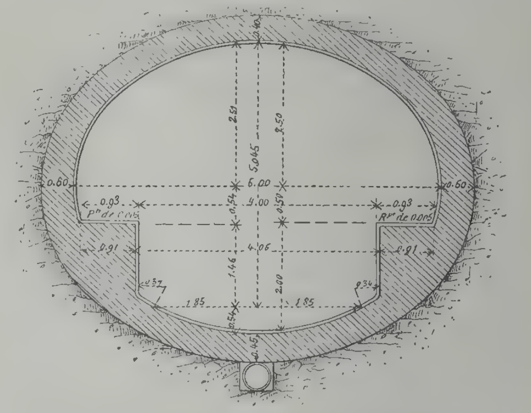


Fig. 1.—Cross Section of Paris Sewer Being Built by Hydraulic Shield System of Tunneling.

A part of the sewer work for the city of Paris comprises the construction of an outlet sewer 4,462.35 m. (14,636½ ft.) long, extending from the Place de la Trinite to the banks of the River Seine. About 1,887.05 m. (6,189.52 ft.) of this sewer are outside of the city limits proper, and at a depth of only 0.4 m. or 0.5 m. (1.31 ft. or 1.96 ft.) below the level of the roadway of an important city streets, the Boulevard National. The cross section if this portion of the sewer is shown by Fig. 1. It was intended at first to build this part of the sewer in open trench, but the great obstruction which such an opening would cause to the street traffic, coupled with a guarantee of M. Chagnaud to do the work by tunneling without any such interruption determined the engineers to change their original plans.

In brief M. Chagnaud proposed to use a shield of special design to suit the conditions which required the construction of a masonry lining, and the safe support of a roadway carrying a heavy vehicle traffic and a double track street railway, operated by Serpollet motors weighing 16 tonnes (35,264 lbs.) each. Ordinarily where shields have been used the lining of the tunnel has been of cast-iron segments, which, as soon as erected, would withstand the thrust of the hydraulic jacks used in driving the shield forward. Green masonry could not be subjected safely to such a thrust and especial provisions had to be made for taking the pressure of the jacks. In this respect and in its provisions for supporting the heavy overhead load the shield used was peculiar.

Figs. 2 and 3 are cross and longitudinal sections showing the construction of the shield. Two elliptical arch girders B B rest on two longitudinal girders C C, and carry an exterior covering or lagging of steel plates 28 mm. (11 ins.) thick. The rear of this lagging terminates in a vertical plane, but the front is visor shaped. Its length at the longest part is 5.25 m. (17.24ft.), of which the visor makes 2.1 m. (6.88 ft.). The longitudinal girders C C rest on two trains of iron rollers K K, and also act as a support and track for a third arch girder D, which is independent of the shield proper, and can be moved back and forward inside of it.

To the arches B B are attached six hydraulic jacks E E, each 0.24 m. (0.787 ft.) interior diameter, which are fed by a battery of four pumps P operated by a small electric motor V, and are double acting. Any one or all of these jacks may be operated at will. At N is the water supply and at S is a sill covered with a 1-m. (03937 in.) steel plate and forming a track for the rollers K K. Altogether the shield weighs about 50 tonnes (110,200 lbs.).

---

*In all these tables the declination is for noon of the given day.

The method of operation is as follows: Steel frames G G, braced together by the I-beams H, are used to support the centers for the masonry arch during construction and also the temporary blocks for the lagging b. Altogether there are 37 of these used, spaced 1 m. (3.28 ft.) apart, and as the work progresses the rearmost frame is regularly transferred to the front and put into use again. The weight of the masonry on these frames—all being braced together—is enough to render the foremost frame firm against the pressure of the jacks, which thrust against it to drive the shield ahead. By this arrangement no thrust comes against the face of the masonry.

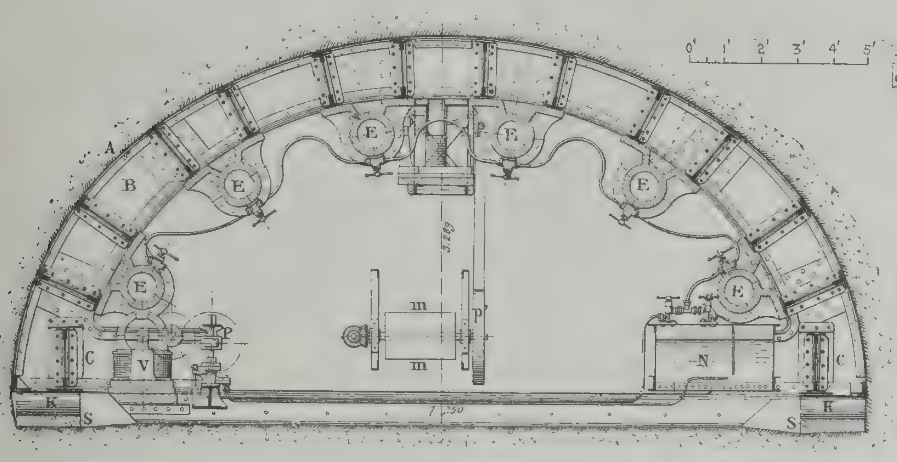

FIG. 2.—CROSS SECTION OF SEMICIRCULAR SHIELD FOR SOFT GROUND TUNNELING.

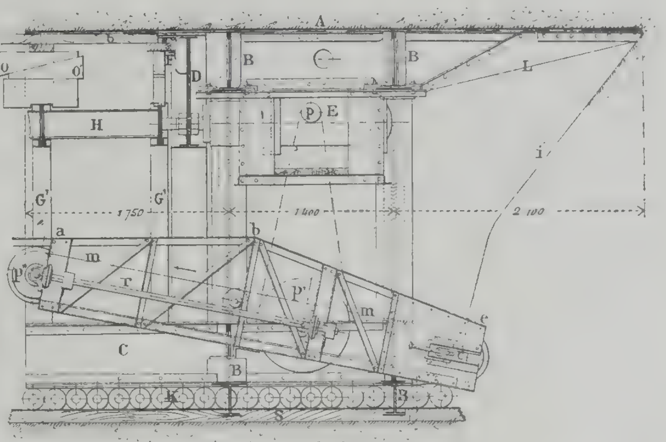

FIG. 3.—LONGITUDINAL SECTION OF SEMICIRCULAR SHIELD FOR SOFT GROUND TUNNELING.

From Fig. 3 it will be seen that the piston rod passes through the girder D, to which it is attached, and abuts against the frame G. As the piston rod is thrust out, the whole shield, with the exception of the arch D, advances and cuts into the sand which the muckers dig out and throw back upon the continuous belt conveyor m m. As the shield advances, the wedges O O are continuously driven so as to make the lagging take up the space left by the skin of the shield which slips from above it. It will be noticed that the forward end of this lagging is carried by the arch D, which does not move during the advance of the shield proper. The shield having been pushed ahead 1 m. (3.28 ft.), which is the stroke of the piston, the stroke is then reversed and this brings the arch D forward into position for a new center G and new lagging. At the same time new wedges are placed over the center G and everything is ready for another advance of the shield.

This reciprocating motion of the shield proper and the inside arch D is the essential feature, as it permits the lagging to be held steady while the skin slips from above it and leaves no void except the thickness of the steel plate which is taken up by driving the wedges O O. Practically no settling of the superincumbent earth is possible if the shield and centering resist distortion.

As stated above the shield weighs about 50 tonnes. Except when loaded vehicles are passing the superincumbent load is small. No very great load thus comes upon the sills S S; indeed it is estimated that this load is only 0.4 kg. per sq. cm. The pressure of the hydraulic jacks is ordinarily 50 atmospheres, but when hard places are met it sometimes amounts to 100 atmospheres. The jacks have a capacity of twice this last pressure. In the sandy earth in which the work is being done the shield can be driven ahead 1 m. (3.28 ft.) in about 15 minutes. The daily advance of the completed tunnel is 7 or 8 m. (22.96 ft. or 26.24 ft.).

The masonry lining is carried on at a little distance in rear of the shield. Centers for the roof arch are placed two at a time upon the metal frames G G, and the upper part of the lining built. The lower half of the sewer is then excavated and the lining built to connect with the completed roof arch. About 900 m. (2.952 ft.) of the sewer had been completed at the time of the publication of the article by "Le Genie Civil," April 25.

* * *

METHODS IN USE FOR THE ANALYSIS OF ORES, PIG IRON AND STEEL BY THE CARNEGIE STEEL CO.

The Chemical Section of the Engineers' Society of Western Pennsylvania recently issued a circular asking for the co-operation of chemists in an effort to collect for publication the methods in general use for the analysis of ores, pig iron and steel. The reports of methods are to be published separately. The first report, now published by the society, is by Mr. John S. Unger, and it describes the methods in use in the laboratory of the Carnegie Steel Co., at Homestead, Pa. As the analysis of iron, steel, etc., is of considerable interest to a large number of our readers, we reprint Mr. Unger's paper in full, as follows:

Determination of Silica in Ores of Iron and Manganese.

To 1 gram of the ground ore in an 8 oz. beaker add 35cc. of HCl (1.20 sp. gr.), cover with a watch glass, and boil gently on a hot plate for 20 minutes. Remove and rinse watch glass and sides of beaker with 15cc. of water, filter off insoluble matter on an 11cm. filter, catching filtrate in an 8 oz. beaker, wash with water until all soluble matter is removed. The filtrate, which should not exceed 90cc., is placed on a sand bath and allowed to go to dryness. The filter is ignited and residue fused with 8 grams of carbonate of soda. The fusion is run up around the sides of the crucible and then the crucible is cooled by dipping cautiously in an 8 oz. beaker containing 35cc. water, finally turning the crucible on its side and leaving it. Cover beaker with a watch glass and add HCl gradually until effervescence ceases. After the fusion dissolves out of the crucible, remove with a glass rod and wash the crucible with water. The solution should not exceed 90cc. Evaporate on sand bath to dryness. When both solutions are evaporated, moisten the residues with 10cc. HCl (sp. gr. 1.20) and leave on bath for a few minutes; then add 20cc. hot water, and filter the first through an 11cm. filter, into a 16 oz. Erlenmyer flask, washing out beaker carefully, then filter the second through the same filter. If the alkaline salts have not all dissolved in the second add 20cc. hot water and stir until dissolved, filter and rinse the beaker with hot water wash, until filter is perfectly free from soluble salts. Ignite the filter in a muffle, cool and weigh as pure silica. The filtrate, which is preserved for further use, should not exceed 150cc.

Determination of Iron in Iron Ores.

To the filtrate from silica (given under silica) add 12 grams of B and A shot zinc and 10cc. conc. HCl and place in neck of flask a small funnel. Let the flask stand for about 20 or 30 minutes or until the iron is all reduced. Should the action on the zinc become feeble add 10cc. conc. HCl. When the iron is reduced test a drop of the solution with a drop of potassium sulphocyanide on a white porcelain plate. If it shows no color or just a very faint pink it is ready for titration. Have ready a 16 oz. wide beaker, a platinum triangle large enough to extend over the edges of the beaker, and a Gooch crucible with a tuft of glass wool ¼ in. thick at the bottom. Rinse the funnel into the flask with a wash bottle and pour the solution through the Gooch crucible, receiving the solution in the beaker. Rinse out flask three times with about 10 or 15cc. of water and wash the Gooch crucible once. To the filtrate in the beaker add 5cc. conc. HCl and place on a hot plate for 2 minutes. The solution will now occupy 225cc. Remove from the heat and titrate with standard bichromate solution, using 3 drops for each test toward the end, and adding the bichromate solution, 5 drops at a time, when almost done. Agitate each test drop by blowing gently and continue the addition of the bichromate until the last test shows an absence of blue precipitate after agitating and standing 30 seconds. The bichromate used, multiplied by the factor, gives the metallic iron.

The potassium sulphocyanide solution is made by dissolving 10 grams of the salt in 100cc. H_2O and is kept in a small bottle provided with a glass cap and a short piece of ⅛ in. glass tubing to be used as a pipette in taking out the test drops. The potassium ferricyanide solution is made by dissolving 0.1 gram of the salt in 100cc. water and test drops are removed as with sulphocyanide. The solution must be made up each day. One drop is used for a test.

The potassium bychromate is made by dissolving 52 grams in 12 litres of water, then shaking well and keeping the stock bottle protected from light.

The porcelain plate is 6 × 6 ins., with 12 depressions 1 in. wide by ¼ in. deep on its surface.

The bichromate solution is standardized by dissolving 3 portions of about 0.3 grams, 0.5 grams and 0.7 grams of perfectly clean soft iron wire of 99.80% pure iron in a 16-oz. Erlenmyer flask (having a small funnel in the neck), in 40cc. dilute HCl by the aid of gentle heat. When dissolved rinse the funnel and sides of flask and make solution up to 150cc. Add 12 grams of zinc and when the iron is reduced, titrate exactly as in case of iron in ore. The weight of the wire taken, multiplied by 0.998 and divided by the number of cc. of bichromate solution used, gives the factor and these factors should agree to the third decimal place.

For iron in manganese ores, the basic acetate precipitate of iron spoken of under manganese is dissolved in 40cc. dilute HCl, the solution made up to 150cc. and treated exactly as in the case of the determination of iron in iron ores.

Determination of Phosphorus in Steel, Pig Iron and Ores.

Dissolve 1.63 grams of steel in a 6 oz. Erlenmyer flask in 30cc. HNO_3 (sp. gr. 1.20). Place the flask over a burner and evaporate over naked flame to 15cc., add to the boiling solution 20cc. chromic acid solution, and again evaporate to 18cc., remove from fire and wash down sides of flask with from 5 to 7cc. H_2O and cool to 40° or 45° centigrade. Add 60cc. molybdate solution, previously filtered and heated to 40° or 45° centigrade, insert a stopper in flask, and shake for 5 minutes. Leave stand in warm place for 15 minutes, then filter through a 7cm. B and A, A grade) filter (previously dried and weighed at 110° centigrade), and wash with a 2% nitric acid solution until free from iron, then twice with 95% alcohol. Dry 20 minutes at 110° centigrade and weigh. Each milligram corresponds to .001 phosphorus.

For pig iron dissolve 1.63 grams, in a 4½-in. evaporating dish, in 40cc. HNO_3 (sp. gr. 1.20), evaporate to dryness on a sand bath. Then place on a burner and heat over naked flame until the mass ceases to evolve red fumes, allow dish to cool and add 25cc. HCl (1.20 sp. gr.), cover with a watch glass and evaporate to 10cc. Add cautiously 25cc. HNO_3 sp. gr. 1.42) and evaporate to 12cc., remove from burner, rinse watch glass and sides of dish, with 12cc. H_2O, filter through an 11cm. filter into a 6 oz. flask and wash with H_2O. The solution should not exceed 50cc. Heat to 40° centigrade, add 60cc. molybdate solution previously filtered, and heated to 40° or 45° centigrade,, shake and finish as for steel.

For manganese ores dissolve 1.63 grams in 40cc. HCl (1.20 sp. gr.) in a 4½-in. evaporating dish, by gentle boiling, then evaporate to dryness on sand bath, add 25cc. HNO_3 (sp. gr. 1.42) and evaporate to 12cc., dilute with 12cc. H_2O and filter through an 11cm. filter into a 6 oz. flask. The solution should not exceed 50cc. Heat to 40° or 45° centigrade, precipitate and finish as in case of steel.

For iron ores if no phosphorus exists in the insoluble residue and the ore is easily decomposed, proceed exactly as for manganese ore. Should phosphorus exist in the insoluble residue, dissolve 1.63 grams in 40cc. HCl (1.20 sp. gr.) in an 8 oz. beaker by gentle boiling for 20 minutes, dilute with 20cc. H_2O and filter into an 8 oz. beaker, washing with H_2O, set filtrate on sand bath and leave evaporate to dryness. Ignite residue and then fuse with 8 grams of Na_2CO_3 and dissolve fusion as for iron in ore, evaporate the solution to dryness on a sand bath, add to each beaker 25cc. HNO_3 (1.42 sp. gr.), and evaporate carefully to 12cc., dilute with 12cc. H_2O and filter both through an 11cm. filter into an 8 oz. flask, using the same filter for both solutions. Wash with H_2O, heat to 40° or 45° centigrade and proceed as for steel.

The chromic acid solution is made by dissolving 30 grams of pure chromic acid in 2 litres of HNO_3 (1.42 sp. gr.), at a gentle heat. It must be made up fresh at least every two weeks.

The molybdic acid solution is made by mixing 100 grams MoO_3 to a paste with 265cc. H_2O, then adding 155cc. NH_4OH (.90 sp. gr.) and stirring until all is dissolved. To this solution add 66cc. HNO_3 (1.42 sp. gr.) stir and set aside for an hour. In another vessel make a mixture of 395cc. HNO_3 (1.42 sp. gr.) and 1100cc. H_2O. Then pour the first solution into the second in a small stream, stirring constantly. Let stand for 24 hours when it is ready for use.

The filter papers for weighing the yellow precipitate are B and A 7cm. "A" grade. These retain the precipitate without it showing a tendency to pass through, and do not contain an appreciable amount of soluble matter, which might be extracted by the acid solution.

The stand for the evaporation over the burners is made of 1 in. angle iron bent and fitted with ¼ inch asbestos mill board, having a 2¼ inch hole over each burner; this supports the flask easily and prevents the solution from baking on the sides.

The drying bath is a copper drum with a coil of 1 in. steam pipe at bottom and fitted with a movable disk, near the top having ½-in. holes, through which the stem of the funnel is inserted, the whole being covered by a lid. Steam is supplied at boiler pressure and a temperature of 110° centigrade with very little fluctuation is constantly maintained.

Determination of Manganese in Manganese Ores.

To the filtrate from silica previously spoken of, add NH_4OH. When almost neutral, add it drop by drop until the solution assumes a redish brown color. When the last drop produces a redish brown precipitate, which does not dissolve on shaking, add 10 to 15cc. of ammonium acetate and bring to a boil. Boil one minute. Then remove and let the precipitate settle, filter through a 12½cm. filter, catching the filtrate in a 16 oz. beaker, wash out flask once with hot water. When the filter has run dry, place the funnel in the flask, and dissolve precipitate in 15cc. dilute HCl (1 to 1), wash iron out of paper and repeat the precipitation with ammonia and ammonium acetate, combining the filtrates. Wash the precipitate 3 times with hot water and reserve for the estimation of iron. To the filtrate add 3 drops of solution of phenolphthalein, then ammonia until pink, then 3cc. in excess. Pass a current of H_2S through the solution for 10 minutes, rinse delivery tube and set beaker on sand or steam bath for 30 minutes, filter through a double-pointed 7 and 11cm. filter, and wash with dilute NH_4HS water. When washed place a clean 12 oz. beaker under funnel and pour over precipitate 40cc. of a mixture of 20cc. hot water and 20cc. of 50% acetic acid, keeping the funnel covered with a watch glass. If the manganese sulphide does not all dissolve, pour the solution through the filter again, wash filter 4 times with hot water, and place beaker on a hot plate. Boil for 15 minutes, dilute to 150cc.; add 15cc. ammonium phosphate, and if a precipitate forms, add a few cc. of HCl until dissolved, bring to a boil and then precipitate by adding NH_4OH, drop by drop until the solution smells of NH_4OH. While precipitating stir constantly to bring the precipitate down in a granular form, filter through a 12½ cm. filter, using suction, ignite in muffle and weigh as $Mn_2P_2O_7$.

The ammonium acetate solution is made by dissolving 120 grams. in 2000cc. water, then filtering.

The ammonium phosphate is a saturated solution of the salt in cold water, diluted with an equal bulk of water.

Determination of Silicon in Pig Iron.

Weigh into a 4½-in. evaporating dish .9333 grams of sample, cover with a watch glass, then add 50cc. of a mixture of 10cc. H_2SO_4, sp. gr. 1.83, and 40cc. H_2O. Place over a Bunsen burner, supporting the dish on a piece of ¼-in. asbestos board, having a 2¼-in. hole in the center. and evaporate until dense, white fumes escape, and the drop of water which condenses on the watch glass falls back into the dish with a hissing sound. Remove dish from fire and let cool for two or three minutes. Then cautiously add 50cc. of a mixture of 10cc. HCl, sp. gr. 1.20, and 40cc. H_2O, place over burner and bring to a boil. Boil gently for one minute, remove from the fire, rinse the watch glass and filter the solution through an 11cm. filter. Wash once with water, then with dilute HCl (1 to 1) and finally with water until free from iron.

Ignite the precipitate in the muffle, cool and weigh. To the residue in the crucible add from 4 to 10 drops pure HFl, depending on the amount of silica present. Drive off excess of acid by heating gently on a hot iron plate, then ignite for two or three minutes in muffle, cool and weigh.

The difference in weight is divided by 2, and a decimal point inserted two places from the right hand gives the percentage of silicon in sample.

Determination of Sulphur in Pig Iron and Steel.

Weigh 5 grams of the sample into a 16-oz. side-necked flask, fitted with a rubber stopper and thistle tube. An 8-oz. beaker of the tall, narrow shape, containing 15cc. of cadmium solution and filled to within 1 in. from top with water, is placed under the delivery tube. Then 90cc. of a mixture of 40cc. HCl, sp. gr. 1.20, and 50cc. H_2O is poured into the thistle tube and the apparatus is placed on a stand made of ¼-in. asbestos mill board, having a 2¼ in. hole at one side and heated by a Bunsen burner. The heating is so regulated that the evolved gases are delivered at about three bubbles per second. As the action grows feeble, the heat is increased, until finally when all is dissolved, the solution is brought to a boil and kept boiling for one minute. The delivery tube is then raised out of the beaker and the flask is set aside.

The contents of the beaker are then poured into a 12-oz. wide beaker, the precipitate is washed out of the beaker with a wash bottle, and 5cc. starch paste are added. 35cc. of a mixture of 40cc. HCl. (sp. gr. 1.20) and 50cc. H_2O are then poured into the absorption beaker and rinsed into the solution in the large beaker. The sulphur is then immediately titrated with standard iodine solution.

The iodine solution is made by dissolving 8 grams iodine and 30 grams potassium iodide in 200cc. cold water and then diluting to about 1850cc. A standard steel is then tested by the method and the result noted, and from this the amount of water needed to dilute the iodine, so as to bring it to the required strength is calculated. After diluting, two determinations are made on the standard steel to see that the iodine solution is exactly right. The iodine solution is made of such strength that 1cc. = .01% of sulphur in the sample. Two litres of standard iodine are made up at once and the solution is preserved in a dark cupboard. The amount actually in use is kept in a special burette having a blackened receiver to exclude light. The stock solution is standardized every week.

The cadmium solution is made by dissolving 300 grams cadmium chloride in 1000cc. hot water in a large bottle and then adding 1500cc. NH_4OH (sp. gr. .90), filtering through a pleated filter into a 12 litre bottle. 6500cc. NH_4OH (sp. gr. .90) are then added to the solution and 3000cc. H_2O. The whole is well shaken when it is ready for use.

The starch paste is made by heating 1000cc. water to boiling point in a 1200cc. flask and adding gradually 10 grams of starch made into a cream with 50cc. cold water. Keep the solution boiling constantly. When all the starch is added boil five minutes, then set aside to cool, decant the liquid, throwing the last 50cc. away.

The solution is made up every three days.

Determination of Carbon in Steel.

One to five grams of the sample are weighed into a clean 8 oz. flask and 200cc. of copper potassium chloride are added, the flask is closed with a rubber stopper and shaken until the precipitated copper is completely redissolved, which is easily detected by the absence of copper covered particles at the bottom of the flask. Remove and rinse the stopper, then filter through a perforated platinum boat, having a layer of asbestos ⅛ in. thick at bottom and held in a platinum holder. Wash the residue twice with concentrated HCl, then with water until all the soluble matter has been removed. Dry the boat for two hours at 90° C., when it is ready for burning. Introduce into the combustion tube, pushing it against the roll of silver foil, start a current of oxygen from the cylinder through the apparatus at 2 to 3 bubbles per second. In the meantime weigh the potash bulb and the small calcium chloride tube filled with solid KOH. Attach the bulb and tube to the apparatus and light first two burners and leave burning for 5 minutes to heat platinum gauze in combustion tube to redness, then light the next burner and leave burning 2 minutes, following this by the others in exactly the same way. When all are lighted leave burning 5 minutes. Then shut off the oxygen and start the air current, being careful to make the change without allowing any back pressure from the air in the room. Aspirate air for 40 minutes, using 1000cc., and weigh.

The copper potassium chloride solution is made by saturating 2 liters of cold water with the salt, adding to the solution 100cc. of HCl (sp. gr. 1.20), then 1 gram of a high carbon steel, shaking until dissolved, then filtering the whole solution into a 2 liter bottle, through an asbestos filter.

The asbestos is prepared by rubbing the ignited fiber through a 20-mesh sieve, aided by a gentle stream of water, receiving the water and pulp in a large vessel, allowing the pulp to settle and drawing the water off by a siphon. Cover the pulp with strong, hot HCl, and digest over night, draw off the acid with a siphon and wash with water by decantation until free from acid, pour into a bottle with water sufficient to cover it, and when needed shake the bottle before drawing out a portion.

The purifying of the air and oxygen is effected in an apparatus having one side fitted to the aspirator bottles supplying the air, while the other side connects directly with the oxygen cylinder. The wash bottles are glass stoppered, filled to ½ height with KOH (sp. gr. 1.30), the attached $CaCl_2$ jars are filled to ½ height with solid KOH, the balance with $CaCl_2$ and a plug of glass wool on top; a Y tube connects each side with the combustion tube.

The combustion tube is of platinum, ¾ in. bore, with a body 20 ins. long, having 3-16 in. platinum tubes 3 ins. long extending from the body. The tube contains a roll of platinum gauze 4 ins. long, filling the bore of the tube and pushed into combustion tube until the anterior end is over the first burner, this gauze is followed by a roll 1½ ins. long, of silver foil inclosed in a piece of platinum foil, which just fills the bore of the tube, and this is then followed by the boat; the tube being closed by a cone-shaped ground joint which is reinforced by bands of nickel.

The combustion furnace is an ordinary 10-burner Bunsen furnace.

The absorbing train is made up of two U-tubes giving a total length in tubes of 44 ins.; these are followed by a Geissler potash bulb containing KOH solution (sp. gr. 1.30), (after a bulb has absorbed about ½ gram CO_2 a fresh one is used), and a 4-in. $CaCl_2$ tube containing solid KOH. The bulb and tube are weighed, and these are followed by an 8-in. $CaCl_2$ tube filled with solid KOH to prevent any CO_2 from the outside air entering the apparatus. The first U tube of the train is filled for the first 5 ins. of its length with granulated silver. This silver is removed from time to time as it becomes dark colored on the surface, ignited and replaced in tube. The silver is followed by 17 ins. of $CaCl_2$. In the next U tube there are 11 ins. of $CaCl_2$, then 11 ins. of anhydrous $CuSO_4$, followed by a plug of glass wool. The $CuSO_4$ is renewed after every 5 combustions. When the U tubes are first filled a combustion is made in the ordinary manner, but no weighings made, the object being to saturate any caustic lime which might be in the $CaCl_2$ used. The entire train is supported on a special support which permits of adjustment in a vertical or horizontal direction.

Determination of Manganese in Steel.

Weigh 200 milligrams of steel into a 2 oz. flask, add 20cc. of 1.20 HNO_3. When dissolved, boil gently for 5 minutes, remove and pour the solution into a 100cc. graduated cylinder. Wash out flask 3 times with H_2O, finally dilute to 100cc. mark. Pour the contents into a 4 oz. precipitating jar and mix by pouring into cylinder or jar at least three times, draw off 25cc. with a pipette into the flask in which the solution was made, add 6cc. HNO_3 (1.20 sp. gr.) from a burette, place on a hot plate together with a standard in which the manganese is exactly known and which has been treated exactly like the steel, and when almost boiling add ½ gram lead peroxide, measured approximately on a small glass spatula, and boil for 3 minutes. Remove, place in a cooling bath, and allow the PbO_2 to settle, which usually requires 15 minutes. Decant the solution into a comparison tube and compare with the standard properly diluted as for color carbon determination.

Determination of Manganese in Pig Iron.

Dissolve as for steel, place a small funnel in the cylinder and filter. Wash the residue thoroughly, being careful not to allow the washings to exceed 100cc., treat the filtrate as in case of steel.

Determination of Nickel in Steel.

Dissolve 1 gram of steel in 25cc. HNO_3 (sp. gr. 1.20) and boil in a 100cc. flask, until solution is complete. Wash contents of flask into a ½ gallon flask containing 700cc. hot water, add 100cc. sodium acetate solution and bring to a boil for one minute. Remove from plate and let settle for 3 minutes, filter through a 38½cm. pleated filter into a litre beaker, allow the precipitate to run dry. To the filtrate, which should be perfectly clear and almost colorless, add 3 drops phenolphthalein, then NH_4OH until pink, place on hot plate and pass a current of H_2S gas through the solution for 10 minutes, remove from the plate and add 12cc. acetic acid (50%), stir and allow the precipitate to coagulate on warm plate for 10 minutes, filter through a 12½ cm. filter and wash with H_2S water made slightly acid with acetic acid. Roast in a platinum crucible, carefully at a low red heat (usually at the front of muffle) until the paper has just burned off. Take out crucible and break up the precipitate with platinum rod to powder, then place in the muffle and ignite for 15 minutes at a bright red heat, cool and weigh. To the crucible add 3cc. (1.20 HCl), cover with a watch glass and warm gently on a plate until the precipitate has dissolved. Wash into a 150cc. beaker with H_2O, add NH_4OH until the solution smells strongly of NH_4OH and filter from the SiO_2 and $Fe_2(OH)_6$. Redissolve precipitate in 3cc. HCl and repeat the precipitation with NH_4OH, wash with hot H_2O, ignite in same crucible and weigh. The difference in the weight gives the NiO. A correction of 5% in the quantity of nickel present is made to provide for the nickel remaining in the basic acetate precipitate.

The sodium acetate solution is made by dissolving 3,000 grams of sodium acetate in 12,000cc. water.

◆

A NEW CONDUIT ELECTRIC RAILWAY SYSTEM.

The strength of public feeling against electric trolley railways has decreased considerably within the last few years, as people have come to understand better the small danger from overhead wires under ordinary conditions, and consequently we hear of fewer schemes for underground conduit constructions than we did a few years ago. There remain, however, enough objections, on account of unsightly poles and wires, accidents from broken wires, electrolysis, etc., to furnish an incentive to inventors to improve upon the trolley line by placing the wires underground. From time to time Engineering News has illustrated and described the most successful of these inventions, and this record is continued here with the illustration of a new conduit system which seems to possess several good features, and which is stated to have worked successfully upon a short experimental line. This system is known as the "K. A. K. surface and subsurface electric system," and is controlled by the firm of Krotz, Allen & Kelly, of Springfield, O. The inventors are Mr. A. S. Krotz, of Springfield, O., and Mr. W. P. Allen, of Chicago, Ill.

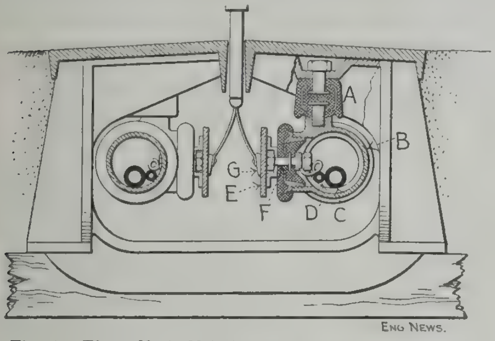

Fig. 1.—The "K. A. K." Conduit Electric Ry System.

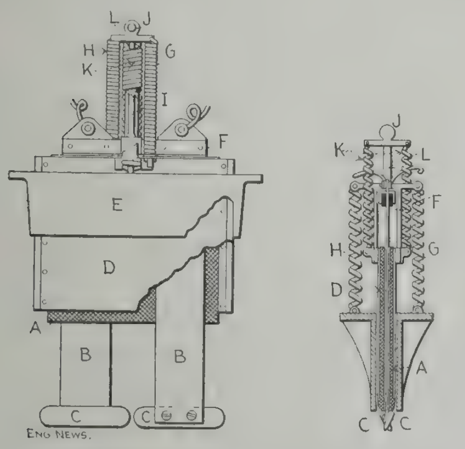

Fig. 2.—Trolley for "K. A. K." Conduit Electric Ry.

Fig. 1 shows the conduit and electrical construction for ordinary street railways. The cast-iron yokes rest on ties between the rails, the top of the conduit being flush with the top of the rails. Between the yokes the conduit consists of a metal casing. From the top of the yoke the insulated hanger A carries the gas pipe B. Inside this gas pipe is the insulated feed wire C. Auxiliary feed wires D, in independent lengths of from 500 ft. to 700 ft., are connected to the main feed wire C, each length of auxiliary wire carrying the current for a corresponding length of track and being connected to the main wire by fuses and switches inclosed in water tight boxes. It will be seen that any length of track can be cut out by simply switching off the current from the corresponding length of auxiliary feed wire. From the auxiliary feed wire the current passes to the contact rail E by means of the bolts F, placed every 24 ft., and from the contact rails it is conveyed to the motor by means of the shoes G.

The foregoing explains the essential features of the system as far as the conduit construction goes. It will be seen that both positive and negative wires are very fully insulated; the feed wires being insulated and inclosed in a water-tight pipe, and the pipe itself being also insulated from the metal work of the conduit. Especial stress is laid upon the efficiency of this insulation by the inventors.

Fig. 2 is a detail of the trolley used. B B shows two springs made of flat steel or spring brass. On their lower ends are attached cast-iron shoes C C for making contact with the conductor rails, as shown in Fig. 1. These shoes can be replaced at a trifling expense. The springs B B, one positive and the other negative, are curved in opposite directions at the bottom, and pass through and are supported in insulating material A which is protected and supported by the steel covering D, which in turn is fitted loosely in the base E, which is fastened permanently to the trucks. Springs B and B, which are fastened together at the top by the insulating fiber strip F, pass loosely through the insulation of casing D, and are held down by the springs G and H, which are attached to the post and cross bar I, J and K. The casing D is in turn held down by heavier springs K attached to the standard L and the base E. Binding posts are provided at the upper ends of springs B B, to which the wires leading to the motors are attached. To raise the trolley from the slot, a lever on the platforms attached in a proper manner to the cross bar J is provided, by which a single pull first raises the springs B B, drawing the shoes away from the rail, and together at the bottom of the casing D, as shown, and raising the casing D, and themselves from the slot. When raised the shoes are clear of the top of the conduit and the car can be moved by any other method of applying the power. This allows of the car being interchanged with lines having overhead trolleys, i. e., the conduit system can be used in the main city streets and the overhead trolley system in the suburbs.

This conduit trolley and the electrical construction in the conduit constitute the principal features of the system being described. To apply it to elevated railways and steam railway lines, the conduits are modified to suit the conditions, but the trolley and feeder construction are exactly the same in principle. Where cars are run in trains each car may have its motor and trolley or there may be a single motor car or locomotive to which the current is carried from the trolleys on each car, current thus being taken from a long length of contact rail. This last feature allows a section of track to be "cut out," say, at the crossing of another track, without interfering with the supply of power to the motor car, as long as the section of track "cut out" is not longer than the train.

Mr. W. P. Allen informs us that an experimental line several hundred feet long has been built at Springfield, O., and subjected to every test possible with so short a line to determine the efficiency of the system. This line has shown that the insulation is nearly perfect, and that snow and rain cause very little trouble. The company now stands ready to take contracts for equipping street railway lines with its system and will guarantee its practical operation.

◆

PROSPECTS FOR RAILWAY CONSTRUCTION AND FOR MANUFACTURING IN CHINA.

We reprint the following review of industrial affairs in China from a report by Minister Charles Denby to the Department of State, dated at Peking, April 6, and just made public. It doubtless gives a more reliable view of the prospects for railway construction in China than the numerous reports of great contracts, concessions, etc., secured by foreigners there which have been published during the past few months in the newspapers:

> The failure of foreign war and internal disturbances to adversely influence trade is noticeable. Notwithstanding the cession of Formosa and the closing of the Niuchwang custom house during several months, the trade of China with both western and Asiatic countries increased and expanded.
>
> The trade with the United States, while less than for 1894, was greater than for any other in the preceding eight years. The exports to the United States in 1895 amounted to $12,168,271; the imports from the United States to $4,028,707, of which more than $2,373,000 were for kerosene oil. It is noticeable that in 1895 the import of Russian oil exceeded that of American oil in quantity and value for the first time in the history of the trade. This is accounted for by the large stocks of American oil imported in 1894 and held over.
>
> The close of the war with Japan was looked forward to by foreigners as the date from which China was to depart from her traditional policy as to internal improvement and development. It was anticipated that this government would enter upon railroad construction, mining, and naval and military systems of great magnitude. While the views of the most enthusiastic have not been realized and China has shown a cautious conservatism, there has been no want of progress. The railroad from Tientsin to the vicinity of Peking has been authorized and is now being rapidly constructed. Great extensions of the line from Tientsin northward into Manchuria have been determined on, and will doubtless soon be undertaken.
>
> As to the general problem of railroad construction, the Chinese Government stands committed to the policy of using Chinese money only. An imperial decree has authorized the formation of native companies for the construction of lines in the south. It is not believed, however, that this policy will avail for lines of any great extent, and it may be predicted that China will resort, eventually, to the aid of foreign syndicates.
>
> The railroad development of China has attracted the attention of American financiers and builders of rolling stock and equipment. Many agents of American firms are now in this country awaiting the adoption of some definite plan by the Imperial Government. At least two combinations of American capitalists, represented here by agents, are prepared to build and equip from beginning to end any railroad system which China may desire.
>
> In the matter of naval and military reorganization, China showed after the war little desire to take immediate steps. Confronted by a debt of 200,000,000 taels* to Japan, and without resources to meet it, the government decided not to pledge its credit for ships and guns which were not immediately needed. The conservatism was a disappointment to many agents of foreign manufactures, among whom were several American firms. The success of Europeans in this line of trade in the past has been due to long representation here and great patience. The high standard of excellence recently attained by Americans in the production of ships, armor, and guns will doubtless enable them, by the adoption of a similar policy, to secure, in time, a share of this business.
>
> The provision in the treaty of peace between China and Japan authorizing the subjects of Japan to engage in manufacturing in the open ports of China, a privilege which inured to the citizens of all treaty powers, seemed to open a wide and profitable field of investment to foreign capital. When the commercial treaty between the above powers came up for discussion, however, the value of the said privilege was considerably restricted by the unexpected assertion by China of a right to levy discriminating taxes on goods manufactured by Japanese at the ports, and also on such goods when shipped inland. This subject was referred to in my dispatch of Jan. 21 last, and the disagreement of the two powers thereon has not yet been settled. The unrestricted right of foreigners to manufacture in China is so fraught with momentous consequences to foreign manufacturing interests that the failure of Japan to secure immunity from taxation for the product of her mills in China would excite little sympathy in manufacturing communities abroad. It would seem, therefore, that dangers still confront foreign manufacturing establishments in this country which no foreign government would find to its interest to remove and that Americans about to embark in manufacturing enterprises here might be advised to take notice of them.
>
> Intimately connected with the subject of manufacturing is the question of exchange. The customs statistical secretary says, in the first paragraph of his report:
>
> > Cheap labor and raw material are abundant, and with the continuance of the advantage which the East enjoys by the fall in the gold price of silver, there is every prospect of China becoming a most important manufacturing country, which will lead to a keen and formidable competition in textiles between east and west.
>
> It is safe to say that it will be many years before native manufactured articles will drive foreign goods out of the market. The silver question cuts both ways. The mer-

---

*The average value of the Haikwan tael in 1895, according to the United States Treasury valuations, was 79.1 cents.

chant in China buys for silver and sells in Europe and America for gold; thus he largely gains. On the other hand, he buys in foreign countries for gold and sells in China for silver. Prices for foreign goods are necessarily raised, but the volume of trade continues to increase. Universal bimetallism would be welcomed by many foreign merchants residing in China, though the sentiment is by no means universal. It is safe to say that scarcely any one favors "free silver" for his own country alone.

THE STRENGTH OF MONIER PLATES.*

The growing use of iron and cement combined in construction has led Mr. T. Grut, Member of the Danish Society of Engineers, to investigate, theoretically, the strength of the so-called Monier plates, where a thin sheet, or combination of rods, of iron is built into the cement. He remarks that the usual method of assuming the neutral axis to pass through the center of the plate, as though the whole was a homogeneous mass, is a superficial one, and proceeds on more rational lines, by taking into account the different coefficients of elasticity of the two materials. That of iron being well known, the investigations have a special interest through the selection of a coefficient for cement. Experiments in Europe, and several by the author are reviewed, and it is concluded that for cement mortar 1 to 3, and half a year old, the coefficients of elasticity for tension and compression are practically alike, and their value lies between 300,000 and 400,000 kg. per sq. cm. (4,266,000 and 5,688,000 lbs. per sq. in.); nearer, however, to the lower limit. It is also noted that these values are considerably higher for the mortar mentioned than for pure cement.

After an extended analytical investigation, the author recommends the following two rules: First, that the neutral axis in a Monier plate, where the iron is placed at a distance of one-sixth the thickness of the plate from its lower edge, be assumed to lie at a distance of three-quarters the thickness from the same edge. In this case the tensile resistance of the cement is not considered; a course which the author believes to be the most prudent. Second, that the iron should not be strained above 525 kg. per sq. cm. (7,465 lbs. per sq. in.). This, the author remarks, is really using a safety factor of four, as the ultimate strength of a Monier plate is at the limit of elasticity of the iron; for as soon as that limit is passed, the expansion of the iron becomes so rapid that the cement, whether it be above or below the plate, can not follow it, but breaks, and the Monier construction, as such, is destroyed.

THE INVESTIGATION OF THE COST OF ARMOR plate ordered at the last session of Congress is being carried on by Secretary Herbert. It is stated that the Bethlehem Iron Co. has offered to supply an itemized statement of the cost of armor plate at its works.

CONVICT LABOR FOR ROAD WORK is being utilized in California and the California Highway Bureau has had a rock crushing plant erected at the penitentiary at Folsom. The convicts quarry the stone and attend to the crusher, and the broken stone is supplied free to road contractors, a check being kept to ensure that the stone is used for the purpose intended.

BOOK REVIEWS.

BICYCLE REPAIRING.—A Manual Compiled from Articles in "The Iron Age." By S. D. V. Burr. New York: David Williams. 8vo.; cloth; pp. 166; illustrated. $1.

This book is designed to be a practical manual for the use of those engaged in bicycle repairs. The various mechanical operations involved in the repairs of the various parts of a bicycle are described in detail, and in such a manner as to be clear to the ordinary workman. While there are many emergencies in repair work which are not touched on by the book, on the other hand we believe hardly any mechanic engaged in this class of work can peruse the book without finding some wrinkle that will be of practical use to him. The book will be found very helpful also by those who reside where bicycle repair shops do not exist, and who are therefore compelled to repair their wheels themselves, if they would not trust them to the tender mercies of the country blacksmith.

The chief criticism we have to make on the book is that its usefulness would probably have been greater if more space had been given to the actual description of methods of repair and less to the description of cheap hand-made devices for doing various jobs. The bicycle repair business has now become important enough for workers in it to afford to buy good tools. In fact, they often cannot afford to spend their time patching up cheap home-made substitutes.

HOW TO BUY LIFE INSURANCE.—The essentials to be considered in selecting a company. Policy restrictions and privileges, digested and classified for ready comparison. Tables showing dividends earned by 32 life insurance companies during the past ten years. By J. H. Lewis, P. O. Box 827, Denver, Colo. Published by the author. Small, 12mo.; cloth; pp. 198. $2.

While this little treatise is upon a subject somewhat aside from those usually discussed in this column, we feel that we can do no better service to our readers than to call their attention to its merits. Of the advantages of life insurance to every man who has others depending upon him for support, it is not necessary to speak here. Every intelligent man recognizes them. But we venture to say that there is no business of such great magnitude which is so little understood by those who patronize it.

Of the people who purchase life insurance, it is safe to say that not one in one hundred attempts an intelligent comparison to determine which of the many companies is the best for him to invest in. Few people ever think of such a thing. They select the company with whose name they are most familiar or the one whose local agent has the best success in winning their ear. It is manifest that a selection made in this way may be a wise one and may be the height of foolishness.

That men of the highest intelligence should be so careless in making an investment of such importance is inexplicable; and, moreover, it is wholly needless. The laws of the various states have so regulated the business of life insurance and enforced such publicity in its operation that any one who chooses may know all there is to be known concerning the merits of the various companies and of the different plans of insurance.

It is a very common fallacy with respect to life insurance that "one company is as good as another," or, to carry it still further, that since the object of all insurance companies is to pay to the beneficiaries of patrons a certain sum at death, that all plans of insurance are equally meritorious. Both these ideas are utterly fallacious; and so we may remark, is another idea, that because the premium rates are practically the same in all the "old line" companies, therefore the cost of a given amount of insurance is the same in all.

In the little book before us, the author describes first, the different plans of insurance and emphasizes the fact that there are actually only two plans, the assessment and the level premium plan. He describes each plainly and fairly and leaves the reader in no doubt as to the merits and demerits of each. The main part of the book, however, is devoted to a comparison of the various "old line" companies. All the various kinds of policies issued are described in detail and tables compiled from the State Insurance department reports show the results of the operation of all the principal companies for ten years past.

We cannot too strongly urge any of our readers who may desire to take out life insurance, to ignore what agents may tell them and instead take a copy of this little work, study the subject of life insurance for themselves and choose for themselves the best plan of insurance and the best company for their needs. A very moderate expenditure of time and study by any intelligent man will enable him to do this, and he can hardly expend either time or mental energy in a more profitable manner.

HEATING AND VENTILATING BUILDINGS.—An elementary Treatise. By Rolla G. Carpenter, M. S., C. E. M. M. E., Professor of Experimental Engineering, Cornell University. John Wiley & Sons, New York, 1895. 8vo.; cloth; pp. 411. $3.00.

The object of this book is to present first a statement of the scientific principles which apply to the subject of heating and ventilation of buildings; second, a collection of tests which give data showing the relation of theoretical principles to practical construction; third, a description of practical methods which are in use; fourth, a description of the methods of designing various systems of heating and ventilating; fifth, a collection of tables useful in designing. The work is arranged in a scientific manner, and the rules of practice are based on scientific reasons modified by such co-efficients as have been obtained by actual tests or experience. The chapter headings give a fair idea of the arrangement and scope of the work, and they are as follows: Nature and Properties of Heat; Principles of Ventilation; Amount of Heat required for Warming; Heat given off from Radiating Surfaces; Pipe and Fittings used in Steam and Hot-Water Heating; Radiators and Heating Surfaces; Steam-Heating Boilers and Hot-Water Heaters; Settings and Appliances; Methods of Operating; Various Systems of Piping; Design of Steam and Hot-Water Systems; Heating with Exhaust Steam, Non-Gravity Return Systems; Heating with Hot Air; Forced Blast Systems of Heating and Ventilating; Heating with Electricity; Temperature Regulators; Specifications, Proposals and Business Suggestions, Appendix, containing References and Tables.

The work is an important addition to the literature of ventilating and heating, and will no doubt take rank with the best treatises on the subject. In future editions we believe it may be improved by considerable enlargement so as to include details and illustrations of recent practice in heating and ventilating modern office buildings, auditoriums, etc., and by a careful revision of the text which will eliminate some unnecessary matter (for example, the C. G. S. system of physical measurements, with its dynes, ergs, etc.) and will give greater precision of language to some of the statements of scientific principles. We have read somewhat carefully the introductory chapters and note below what appears to be defects that may be remedied in the next edition.

Concerning the British thermal unit and the mechanical equivalent of heat the author says, page 4, "In English-speaking countries the heat unit is that required to raise one pound of water from a temperature of 62° to 63°." It is in fact almost universally defined as the heat required to raise a pound of water one degree at its temperature of maximum density, or from 39° to 40°, although some early writers have given the temperature as 32° to 33°, and a few recent ones 62° and 63°. Peabody, Thermodynamics, p. 5, says:

> A calorie is commonly defined as the heat required to raise one kilogram of water from freezing point to 1° C., and a British thermal unit that required to raise one pound from 32° to 33° F. In our work, for reasons that will appear in the discussion of the specific heat of water, we shall choose 62° F. as the standard temperature, and shall define a British thermal unit as the heat required to raise a pound of water from 62° to 63°. This statement is subject to the same indefiniteness as the thermal scale from which it is derived. The true value can be defined only after a logical thermal scale is developed.

For other references on this matter see Wood's Thermodynamics, 5th ed., p. 3, and Trans. Am. Soc. M. E., vol. xiii., p. 351.

The author says further, on p. 3, concerning Joule's figure, 772, for the mechanical equivalent of heat, "Later investigation has amply confirmed this result. This value reduced to a temperature of 62° F. and for this latitude is increased 6 ft.-lbs., so that at present the work equivalent of one heat unit is generally regarded as 778 ft.-lbs." The fact is that the corrections for temperature and latitude are by no means as great as 6 ft.-lbs., and the later investigations referred to, no doubt those of Rowland, show that Joule's original figures must have been considerably in error. The correction for latitude is only about 1 ft.-lb. or 0.15%, and the correction for temperature is uncertain, and runs in opposite directions, according to whether we take Regnault's or Rowland's figures on specific heat of water. The correction for the difference of temperature between 39° F. and 62° F., according to Regnault, is only about 0.06%. Wood's Thermodynamics, p. 25, says, concerning the corrections:

"If the mathematical equivalent of heat at 60° F. were 774.1, then at 39.1° F. or, say 40° F., it would be 774 (nearly), and reduced from the latitude of Manchester to that of New York, it becomes 774.8, nearly; and if the entire margin of error, 1-400, be positive and applicable to this number, the value would be 776.7, or, to the nearest integer, it would be 777." Prof. Wood says further, "It is apparent that the old value 772 is much too small, and 774.1, recommended by the committee of the British Association (1876) is not sufficiently large. According to Rowland's experiments (1880), the British thermal unit is about 784 ft.-lbs. per degree on the air thermometer, and nearly 779 on the mercurial thermometer." He then selects from these and other data the number 778, as being probably within 1-300 of the actual value for the mercurial thermometer at the latitude of New York.

On p. 43 it is stated that air expands 1 part in 460 for each degree of increase of temperature, while on p. 6 it is stated that when air is at a temperature of 32° F. its volume is reduced 1 part in 492 each time that the temperature is lowered one degree. Both of these statements lack precision, and the first is incorrect. A correct statement would be that air expands 1-492 of its volume at 32° for each increase of temperature of 1° F., and contracts 1-492 of its volume at 32° for each decrease of 1° F.

Another peculiar definition of Prof. Carpenter is that of the C. G. S. unit of force, the dyne, which he says is 1 gramme moved so as to acquire a velocity of one centimetre per second. What he probably means to say is that it is that force which, if applied constantly to a free mass of one gramme for one second, would give it an acceleration of one centimetre per second. He also says "the force of gravity in latitude of Paris is 32.2 ft." The measurement of a force in feet is, to say the least, unusual. The physical constants defined in the beginning a work of this kind should certainly be defined with more precision and clearness of language. Another sample of the author's style in his introduction is the following: "Heat has two qualities which correspond in a general way to intensity on the one hand and to quality on the other. The intensity of heat is termed temperature; this can be measured by a thermometer, but, except in scientific definitions no name has been applied to designate the unit quality of heat (the term entropy is now applied in scientific discussions to this property) and there is no method of measuring it directly, although it is of as much importance as temperature." A lack of scientific precision of statement and of clearness in expression characterizes much of this introductory chapter, and it might be improved by careful revision.

---

THE SAVAGE RIFLE has been selected as the weapon for the New York militia by the Commission appointed to examine the weapons offered for this purpose, consisting of Albert D. Shaw, Robert H. Thurston and E. W. Bliss. The gun is the invention of Mr. Arthur W. Savage, Supt. of the Utica Electric Ry. Co., and is manufactured by the Savage Arms Co., of Utica. Its magazine holds five cartridges which are held in a magazine similar to a revolver cylinder, so that there is no possibility as in the tubular magazine of a cartridge being exploded by the impact of the one behind it against its primer. There were twelve guns in the competition, and the Krag-Jorgenson and Lee-Metford weapons, the new standards of the U. S. Army and Navy, respectively, were also tested, but were found inferior to the Savage gun. Under the law providing for the selection of a new weapon, the Adjutant-General of the state of New York is authorized to contract for 150,000 of the new rifles, at a price not to exceed $20 each.

NO MORE HIGH SMOKESTACKS are to be used on the U. S. naval vessels. The high stacks on the "Brooklyn" and "Iowa" were adopted by Engineer-in-Chief Melville to increase the draft and lessen the use of the forced draft. The line officers, however, are said to oppose the high stacks, on account of their appearance, and consequently they will have to go.

HEAVY ORDNANCE is being placed in position to command the entrance to New York harbor. At Willit's Point, L. I., the work of mounting two of these large guns is in progress. They are 30 ft. long, 10 in. bore and weigh 30 tons each. The steel projectile weighs 575 lbs. and requires 250 lbs. of powder. Each gun can be fired at intervals of three minutes. After the discharge the guns disappear behind the parapet for reloading. In practice shooting the target is to be set six miles away.

SYSTEMS OF FIRING HIGH EXPLOSIVES with safety are to be tested by the naval ordnance bureau, according to Washington press despatches; and it is stated that $50,000 is available for carrying out the tests. Devices are invited from inventors both in and out of the service.

THE HASKELL MULTI-CHARGE SYSTEM is again to be tested, the Board of Ordnance and Fortifications having furnished funds sufficient to give the gun a test of 20 rounds. The gun to be tested is of 8 ins. caliber and has two auxiliary powder chambers attached to the lower side of the barrel. The 6-in. gun of this type which was tested some years ago and proved a failure was provided with four auxiliary powder chambers.

COMPLAINTS OF EXCESSIVE CHARGES for the transfer of grain from lake vessels to canal boats at Buffalo, and from canal boats to elevator or vessel at New York, are again made by the canal boatmen. In an appeal to the New York Produce Exchange the canal boatmen of Buffalo say:

> The result of such unjust methods on the part of the railroad and the wharf trust has been the accumulation of nearly 400 canal boats at this port, or nearly half of the entire diminished canal fleet is here to-day, unable to obtain cargoes at the low rate of 3¾ cts. a bushel on wheat, 3½ cts. a bushel on corn and 2⅜ cts. a bushel on oats to New York, out of which we, the canal carriers, must pay trimming, tugging, insurance on cargo and scalpage here, Hudson River towing, wharfage and trimming cargo at New York; also we must make good the shortage in cargo. After these deductions it leaves us about 2½ cts. a bushel net on wheat to run and man our boats. If we are lucky we will obtain a west-bound cargo to Buffalo at 45 cts. gross ton, free in and out. If we cannot secure an up-freight we are compelled to come to Buffalo light. On the other hand, the charge for transferring grain direct from the lake vessel to canal boats at Buffalo is 1 3-10 cts. a bushel, and for like service at New York it is 1 5-10 cts. a bushel, or, at both ports the extortion amounts to 2 8-10 cts. a bushel. or a clean gouge at both ports of plump 2 cts. a bushel against canal grain, if the grain is stored on its way to the world's markets, the extortion doubles up in short order. Contrast this robbery with the next-to-nothing terminal charges at the railroad docks of New York's fierce competitors and who can wonder that the trade that legitimately belongs to New York is like water seeking the lowest level, not to say anything about the full cent-a-bushel differential railroad rate against your port? The result of this gigantic railroad conspiracy against New York and New York's canal is to keep boats here in idleness from fifteen to twenty days waiting for cargoes, while at the same time competing railroads are flooded with grain. It may be truthfully stated that about all the grain and other freight that the canal and New York get is that portion that slops over the railroad grain elevator dams, as aforesaid.

It must be confessed that a charge of 1.3 cts. a bushel for transferring grain from a steamer to a canal boat does look a little steep compared with a net rate of 2½ cts. a bushel for carrying the same over 400 miles of canal and river navigation.

SHIPMENTS OF GRAIN from Buffalo to New York by rail and canal respectively are reported as follows for the period from May 1, the opening of navigation, to July 2, this year and last year.

1896.	Wheat.	Corn.	Oats.	Total.
By rail, bushels.	3,605,900	5,453,350	6,672,200	15,732,050
By canal, "	4,332,700	583,100	4,190,000	9,105,800
1895.				
By rail, bushels.	2,943,350	4,607,850	3,383,200	10,934,400
By canal, "	1,514,000	110,400	2,440,200	4,064,600

It will be seen from the above that the canal is carrying, so far, over twice as much grain as a year ago. It will be remembered, however, that the shipments by canal in the early part of last season were phenomenally small.

THE EXPORTERS' ASSOCIATION OF AMERICA is the title of an organization recently formed to co-operate in securing foreign markets for American manufacturers. Its officers are: President, Addison H. Nordyke, President of the Nordyke & Marmon Co., of Indianapolis; Vice-President, Jas. W. Cooke, New York city; Treasurer, A. M. Dolph, President American Laundry Machinery Co., Cincinnati, O. The headquarters are in the Morris Building, New York city, with Mr. Andrew H. Power, the secretary of the association, in charge. All responsible manufacturers and exporters and foreign buyers are eligible. The dues are $100 per year. Members have the privilege of using the association's rooms as headquarters while in New York, receive weekly reports of exports of goods in their line, and reports of financial standing of firms in foreign countries when requested, and have the consular and custom-house work in connection with exports attended to. The members of the Board of Governors besides the officers named above are C. H. Hutchins, President of the Knowles Loom Works, of Worcester, Mass.; A. H. Overman, President of the Overman Wheel Co., Chicopee Falls, Mass., Carl F. Lunkenheimer, Treasurer of the Lunkenheimer Co., Cincinnati, O., and others.

AMERICAN BICYCLE MAKERS are cultivating the export trade assiduously of late. In the month of May the value of bicycles and bicycle parts exported was $220,176.

THE MOST SERIOUS RAILWAY accident of the week and of many weeks occurred near Logan, Ia., July 11, on the Chicago & Northwestern Ry., and was a head collision at a curve between an excursion train and a fast freight. From press reports it appears that the excursion train left Logan without orders. It was running very slowly when struck by the freight, whose speed was about 30 miles per hour. The baggage car was driven back through the first coach, killing or injuring almost every one in it. Passengers in the other coaches were not hurt. Thirty-three persons were killed and 37 were injured. On July 12 an excursion train on the Chicago & Northern Pacific, at Altenheim, Ill., ran into an open switch and collided with two freight engines standing on the switch; five persons were killed and six were injured. As in the Logan disaster, the baggage car telescoped the first coach. This coach was a light one used ordinarily for suburban traffic. Had it been as heavy as the remaining ones, there would probably have been no serious results, as the train was running so slowly that passengers in the rear cars did not realize that a collision had occurred.

At Wilkes Barre, Pa., on July 13, an express train on the Lehigh Valley Ry. while rounding a curve struck a cow. The train was derailed and the locomotive rolled down a high embankment; three passenger coaches were thrown upon their sides; one person was killed and 19 were injured. The derailed train is stated to have run over 200 yds. on the ties.

AN ELEVATOR ACCIDENT occurred in an apartment house at Adams and Dudley streets, Boston, Mass., July 10; workmen in the building had been accustomed to let themselves down governing the elevator by the brake after steam had been turned off. At the time of the accident 13 men crowded into the car when it was 60 ft. from the ground; the brake refused to work and the car fell the entire distance. All those in the car were injured.

ACCIDENTS ON THE BROADWAY CABLE RAILWAY, at the 14th St. curve, in New York city, have attracted much attention of late. The company has always run its cars around this curve at the full speed of the cable, claiming it was impossible to slacken the grip while the car was rounding the curve. So many accidents have resulted and so much public complaint has been made, however, that the company proposes, it is said, to introduce an auxiliary cable to operate cars on this curve. The Board of Aldermen has an ordinance before it limiting the speed on curves to four miles an hour.

THE TIDAL WAVE which visited the coast of Japan on June 15, appears from the fuller accounts now at hand to have been even more destructive than at first reported. The number of lives lost may be placed in round numbers at 30,000. The United Press correspondent at Tokio on June 26, stated that the totals had then reached 29,073 killed, 7,737 wounded, and 7,844 houses washed away or wrecked. It is an excellent showing of Japan's progress in civilization that it should be possible to obtain such detailed figures of the extent of so great a calamity. The cause of the tidal wave appears to have been some earthquake or volcanic eruption beneath the sea at some distance off the Japanese coast. While this occurrence ranks among the greatest disasters of modern times, its record of fatalities is not the largest, as has been claimed by the daily press, but is exceeded by the loss of life due to the breaking of the levees of the Yellow River in China in 1887, and we believe by some others. An interesting summary of great disasters was given in our issue of July 6, 1889.

THE RUNAWAY OF AN ELECTRIC CAR, on a steep grade on 39th St., Brooklyn, on June 7, last, has been reported upon by the New York Railroad Commission. The board recommends that passengers be prohibited absolutely from riding on the running-boards or side steps of open cars and that all cars operated over grades steeper than 5% should be equipped with some sort of auxiliary brake, and in ascending such grades, conductors should be required to remain on the rear platform to protect the trolley pole or assist at the brakes, in case of emergency. The board appears to have overlooked the fact that if such a rule is put in operation it should apply as much to cars descending such grades as to those climbing them. There is much more danger in coming down a long or steep grade than in going up it.

WATER POWER DEVELOPMENT at Garvin's Falls, N. H., 13 miles from Manchester, is proposed. At this point the Merrimac River falls 30 ft., and with proper storage 4,500 HP. is said to be available. Among those interested are W. A. Russell, J. M. Wheaton, W. A. Tucker and Philip Y. Saltonstall, of Boston.

THE EXTENSION OF THE WHEEL PIT of the Niagara Power Co. at Niagara Falls, was begun on July 9, and will be prosecuted by double shifts until completed.

THE CLIFF PAPER MILL at Niagara Falls, illustrated in our issue of March 26, began running on July 11, with electric power developed by the water-wheels and generators in the power house at the base of the cliff.

TESTS OF A BOILER of the Cahall vertical water-tube pattern were made at the works of the Armstrong Cork Co., Pittsburg, Pa., on May 4 and 5, by Thos. H. Pray, Jr., of 95 Milk St., Boston. The boiler was rated at 250 HP., and notwithstanding that it was run on the first day 3% above its rating, and on the second day at 66% above, the steam in both cases showed a large amount of superheating, 46° on the first day and 26° on the second day. The evaporation from and at 212° per lb. of combustible on the first day was 13.9 lbs., and on the second day 11.7 lbs. Pamphlets containing the detailed figures of the tests will be sent on request by Messrs. H. E. Collins & Co., of Pittsburg, Pa.

THE BIDS FOR A NEW WATER SUPPLY FOR JERSEY City, submitted recently by the Rockaway & Hudson Water Co., is reported as about to be formally rejected. It is said that bids will again be called for soon. If this is done it will be the fifth or sixth call within the past four years.

ELECTRIC TRANSMISSION OF WATER POWER AT PELZER, S. C.

The accompany views show a large water-power plant recently installed for the Pelzer Mfg. Co., of Pelzer, S. C. The plant is located on the upper Saluda River, in the western part of the state. The power house contains five pairs of 39-in. horizontal Victor turbines each pair coupled direct to a 1,000 HP. generator and regulated by a Giesler electro-mechanical governor. The electric current which is thus generated is transmitted to the cotton mills of the corporation, located about 3½ miles away. The electrical transmission was installed merely for the sake of locating the factory on the most eligible site. It was deemed cheaper to carry the power to the factory than to choose a less favorable location for it. The dam and power house were built by W. A. Chapman & Co., of Providence, R. I.; the electrical machinery was furnished by the General Electric Co., and the turbines and other apparatus for the water-power development by the Stilwell-Bierce & Smith-Vaile Co., of Dayton, O.

DAM AND POWER-HOUSE FOR WATER POWER DEVELOPMENT WITH ELECTRIC TRANSMISSION AT PELZER, S. C.

BURNSIDE SHOPS, ILLINOIS CENTRAL R. R.

(With inset.)

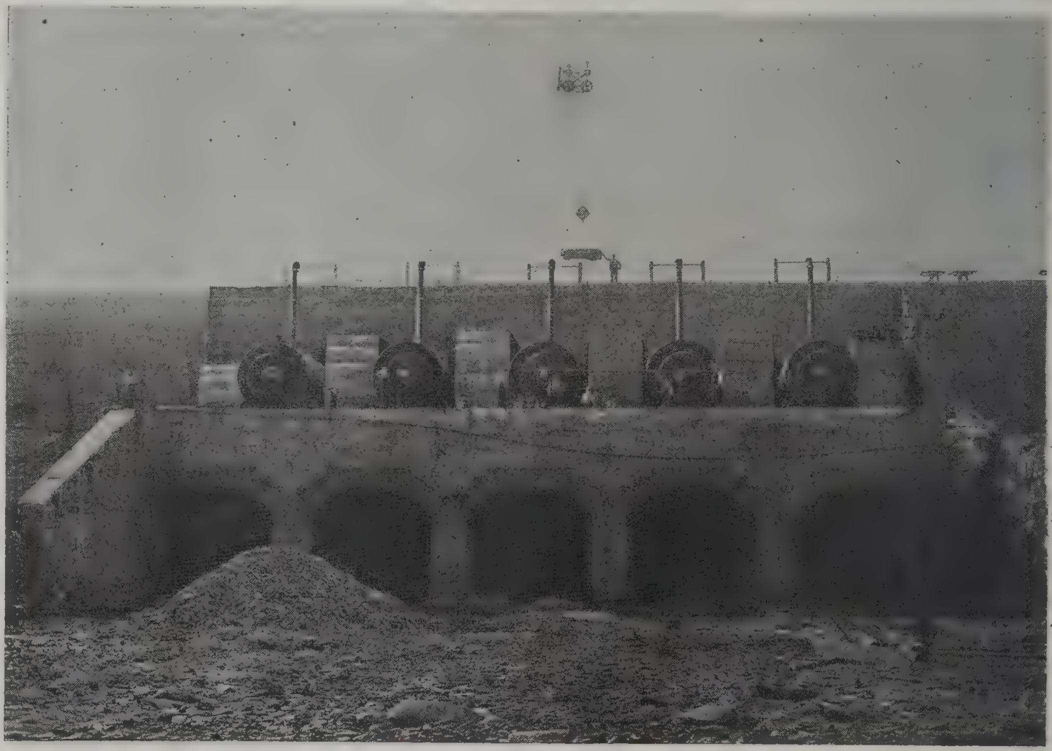
II.

Locomotive Shops.

In the article describing and illustrating this notable railway shop plant, published in our issue of June 18, the ground constructions, minor buildings, and the smallest group of main buildings were considered. In the present article we take up the construction of one of the larger groups of buildings forming the locomotive or metal-working shops. Each building will be described in such detail as the importance of its structural features may seem to warrant. The buildings devoted to locomotive and metal-work are three in number, viz.: a machine shop, blacksmith shop, and roundhouse, and are all located to the south of the oil house, store house and boiler house. All of these buildings were built in 1892 except the blacksmith shop addition, 254 1-6 × 110 ft., which was built in 1895.

Machine Shop.—The machine shop is 552 ft. 2 ins. long and 160 ft. 3½ ins. wide out to out of walls, and is covered by a double roof, as shown by the cross-section Fig. 12. Fig. 13 is a diagram plan of one end of the building, and is inserted to aid in explaining the character of the construction. The opposite end of the building is exactly the same. Turning to Fig. 12 it will be seen that two triangular trusses cover the building. The outer ends of these trusses rest on the side walls and the inner ends on a row of columns which extend lengthwise down the middle of the building. Details of the roller bearings at the wall ends and the inner end truss bearings are shown by the drawings. The west half of the building is open to the roof, and is designed to have an overhead traveling crane. It is into this half of the shop that locomotives from the transfer table are run for repair, there being a series of 24 transverse tracks, each with its pit between rails, for this purposes. The east half of the building is given up to machine tools and machine work, and there is overhead the framework shown by Figs. 13 and 14, which was designed to be floored over, except in the center, and to be used for lighter kinds of work, when the demands of the company should require greatly increased plant, but at present it is used to carry the shafting, a small crane, air hoists, etc. The various parts of this framing and their purposes can be ascertained by inspecting the reference letters and titles in Figs. 12, 13 and 14.

The structural features of the machine shop having been explained, attention may be turned to the equipment for doing work. The power generators may be taken up first. These consist of engines and dynamos, and are all located in a small attached building or annex on the east side of the shop. There are in this building one 200 HP. Bullock-Corliss engine for running the shafting from which all machinery is driven; one 150 HP. and one 50 HP. Buckeye engine, and one 100 HP. Ideal engine. These three smaller engines are used to drive two 80-light and one 40-light arc dynamos and two incandescent light dynamos, operating about 1,000 16-c. p. lights.



HORIZONTAL TURBINES IN POWER HOUSE AT PELZER, S. C.

To enumerate the various tools used would be of little value, and all that need be said is that the equipment is ample for constructing and repairing all classes of machine work for locomotives and cars. To handle material there are hand and power cranes of various sorts, air hoists, and push cars and trucks. The air for the hoists is obtained from the mill building power house, as will be described further on. All machine tools are located in the east half of the building, and the erection is done in the west half, which is open clear to the roof. Facilities for the erection of 24 engines at one time are available.

Blacksmith Shop.—Under the roof of the large blacksmith shop building, which covers an area of 71,960 sq. ft., are a wood working shop, a boiler shop and the blacksmith shop proper. The main building, 440 ft. long and 100 ft. wide, runs north and south, and the addition, 254 ft. 2 ins. long and 110 ft. wide, joins onto the north end and extends west. Beginning at the south end of the main building the first 100 ft. in length is used as a wood working shop for locomotive wood work. A wooden partition extends transversely across the building and divides the wood working shop from the boiler shop, which takes up the next 200 ft. of the length of the main building. At the north end of the boiler shop is a brick partition, and beyond this the main building and the addition or the blacksmith shop proper.

The structural features of interest in this building are confined principally to the roof trusses. Owing to fear of delay in securing steel the trusses for the main building were made of wood, and of the design shown by Fig. 15. The main or center truss has a span of 51 ft., and is carried on cast-iron columns, extending in two rows lengthwise of the building, and 25 ft. 9 ins. from the outer walls. Between these two rows of columns and the outer walls the space is covered by steel trusses. A raised cupola, with side lights, runs the entire length of the wood-working and boiler shops, but over the blacksmith shop the skylight is replaced by ventilators for obvious reasons.

The interior arrangement of the boiler and wood shops calls for but little mention. Entering them from the east side are a series of tracks, which are connected with the locomotive transfer table. Between the interior rows of columns carrying the main roof truss are longitudinal, wooden trusses, designed for a traveling bridge crane, and there are also various cranes and jacks located at different points where needed. The power to operate the machinery is supplied by a 100 HP. Westinghouse standard engine.

The blacksmith shop addition is of later construction than the main building, and the character of its roof construction is entirely different, as is shown by the general plan and elevations in Fig. 16. These drawings show the design and construction in sufficient detail with the exception perhaps of the connection details between the old and new buildings. Across the end of the

old building extends a plate girder carried by the side walls and two intermediate columns, which supports two of the roof trusses of the addition and also the brick end wall of the old building, as shown by Fig. 17.

The interior arrangement of the blacksmith shop addition calls for no particular mention.

Round House.—The round house is a ring shaped building, 316 ft. outside diameter and with a circular interior court 166 ft. in diameter, in which is located the locomotive turn table. Forty locomotives can be stored in the building at once. The walls are of brick and the roof is carried by wooded trusses which have no features demanding particular mention.

The foregoing description with the illustrations give the essential structural features of the locomotive shops of the Burnside plant. The drawings should be studied in particular since care has been taken to avoid repetition of information given by them in the descriptive matter. In a succeeding article the car shops will be described in detail.

For the information from which this article has been prepared we are indebted to Mr. John F. Wallace, M. Am. Soc. C. E., Chief Engineer, and Mr. H. W. Parkhurst, M. Am. Soc C E, Engineer of Bridges and Buildings, Illinois Central R R.

A SMALL ASPHALT-LINED RESERVOIR AT INDIO, CAL.

By J. B. Lippincott.

There is a small asphalt-lined reservoir at Indio spurr, four miles east of Indio station, which is in the Colorado desert west of Yuma. Its length is 88 ft., and its width is 48 ft. on top, and its depth is 4 ft. Its inner slopes are approximately 30° from the vertical, or steeper than 1 to 1. It was built in 1892 under the general direction of Mr. Sutherland Hutton, an asphalt expert and contractor, of Los Angeles, Cal. The sides and bottom were made of asphalt concrete, 3 ins. thick, which was tamped into place while hot with irons. The sides are floated with a coating of asphalt and carbonate of lime, approximately ⅛-in. thick. The sides would have been better with more slope, 2×1 being preferable. An earthen bank was made from the material excavated, 4.5 high and 4 ft. wide on top, with an outer slope 1½×1, the material being sandy loam.

Arroyo Grande (San Louis Obispo) asphalt, 76% pure, costing $25 per ton in 1892 (now $15), was used. It was fluxed with 40% "G grade" asphalt (costing $14 per ton), refined from maltha which will stand 350° flash test. The asphalt concrete, "because of the absence of sand in the locality," was mixed in Los Angeles, the proportions being: Asphalt, 15%; sand, 20%; gravel, 65%. It was cast in blocks, shipped, reheated, laid on this earthen bank and tamped into place behind boards or wooden forms.

Further experience in making asphalt concrete is said to indicate that a much smaller percentage of asphalt should be used, good concrete having been made with as low as 5% of asphalt. Enough asphalt should be used to make a bond in the material and no more, large amounts making the concrete soft under high temperatures. The ideal should be perfect mixing and a low percentage of asphalt.

The writer has seen concrete that was said to have been made of 5% of asphalt and of sand with quartz and granite pebbles of from ½ to 1 in. diameter, in which, under the hammer, the pebbles would go to pieces before the bond would yield. The surface of the concrete in this reservoir was floated with a composition of asphalt and carbonate of lime. The greatest skill and care has to be used in this portion of the work. If the liquid asphalt is heated to too great a temperature it will crack, and if not high enough it will run. The requisites of each case have to be considered and the heat adjusted to them. The liquid asphalt on the side has done some running, but it was found that the sand which was drifted by the lodging on and adhering to it stiffened it and held it in place, which would suggest that a sand blast applied to asphalt coating while it was still hot would not interfere with its imperviousness and would keep it from running.

This reservoir, which is uncovered, has stood temperatures in the shade of 123° for several days, and as the reservoir is emptied every other day, the entire asphalt coating is alternately exposed to and shielded from the direct rays of the sun.

At the ends of the boards or forms, where the concrete was joined to the next abutting layer, cracks of considerable size appeared, which were closed with the liquid asphalt. Coarse grass grows with considerable vigor through the concrete, giving trouble. Since first constructed, this reservoir has never been repaired, has been in constant service and has not leaked. It was built for Mr. C. H. Gale, of Indio. It is filled from two 500-ft. artesian wells, with 5 and 8-in. casings, respectively. Its capacity is about 84,000 gallons, and it is used in irrigating 10 acres of land.

The following is a statement of cost:

Prepared asphalt concrete, 40 tons (2,000 lbs.) at $8	$320
Freight on above	140
Labor	140
Plant (kettles, etc.), not valued	....
Dressing after laying	100
Total cost	$700

The total area of the asphalt concrete was 4,700 sq. ft., making the cost 14.9 cts. per sq. ft.

A PROPOSED STANDARD SPECIFICATION FOR PORTLAND CEMENT.

An interesting paper has recently been prepared by Mr. Wm. J. Donaldson, of Philadelphia, the object of which is to urge the adoption by the United States of a standard specification for Portland cement, the use of which should be required on all work done under the direction of officers of the corps of engineers, and also by the Navy, the Supervising Architect's Office, etc.

Mr. Donaldson sums up present conditions as follows:

1. Lack of uniformity.—The specifications now in use on the various branches of government work show that they have been drawn up by the different engineers in charge of the various departments; with few exceptions they show great difference as to requirements for strength, which is one of the essential features. Some specifications advertise brands alone, without specifying any requirements. The majority of specifications call for no tests on the stability or, in other words, the constancy of volume; few provide for tests on mortar—sand with cement—one of the most vital considerations in determining the true value of cement. The neat tests appear to govern those specifications in which a requirement is asked for; a test which accepted authorities have rendered obsolete and of little value. Slight consideration is taken of fineness, upon which the cost of work largely depends.

2. Low requirements.—Considering first the question of fineness, where such provision is made, in the majority of cases the No. 50 sieve, containing 2,500 meshes per sq. in., appears to represent the standard. Some few specify the No. 100 sieve, containing 10,000 meshes per sq. in., but in all of which the provisions for the minimum percentage of residue asked for, appears to have been taken from specifications made years ago, long since fallen into disuse. As to the strength, some specifications for Portland cement call for minimum tensile strength equalled and surpassed at the present time by the best American natural cements, while the highest provide for a strength far below the performance of the best brands.

3. Acceptance based largely on commercial reputation of brand.—Where brands are specified, the policy followed appears to be a selection of some brand or brands, which have been manufactured for some years—usually foreign cement—in which case two or more brands of Portland cement of entirely different quality are found side by side. Where provision is made for the substitution of other brands, their acceptance is based on their equality, in which the standard of quality is not defined, and unjustly left to the discretion of the engineer.

He then presents his reasons for the adoption of a standard specification by the government, and instances as an example the standard specifications adopted on the Continent of Europe by the congress of cement testing laboratories of Germany, France, Austria, Belgium and Switzerland. The following are the specifications proposed by Mr. Donaldson for adoption as standard. It will be noticed that they are exceedingly full and detailed, and are unique in that the method in which the tests shall be made is fully laid down:

Quality.

Cement.—All cement used to be well seasoned Portland cement, and must conform to the following requirements and be capable of passing the tests herein specified. Manufacturers to guarantee that all cement has been seasoned, or subject to aeration at least 30 days before leaving the works.

Manufacturers to furnish certified tests, from their laboratory, on every car load when shipped; such tests to show they pass the stated requirements, but which shall in no wise be a guarantee of acceptance by the government. This provision acting only as a guide to the cement manufacturer, as acceptance or rejection of cement will be made on government tests.

Packing.—Cement to be packed in strong and well coopered barrels, 400 lbs. gross, or in strong cotton duck bags, three or four bags to the barrel, and 380 lbs. of cement to the barrel.

Sampling.—Samples to be drawn from at least 10% of every one 100 barrels received, the government reserving the right to sample every barrel. Samples to be drawn from the interior of barrel or bags by an iron tube (after the pattern of a molasses gager), and thoroughly mixed as one sample. Tests to be made from the average sample taken from 10 barrels, representing the lot of 100 barrels sampled. Acceptance or rejection to be made as the tests meet or fail to meet the requirements.

Chemical composition.—Full chemical reports to accompany each shipment, the government reserving the right to analyze every sample taken, which must conform to the following requiremnts, and be a tri-calcic silicate cement:

Lime	62 to 66%
Silica	20 to 22%
Sesquioxide of iron and alumina	8 to 12%
Magnesia	not over 3½%

Sulphuric acid....not over 2%, for slow setting cement.
Sulphuric acid, not over ½ of 1%, for quick setting cement.

Time of setting.—A cake of neat cement to be moulded on glass to determine time of setting:

Slow setting, initial set to be over 30 minutes.
Final set to be not over 12 hours.
Quick setting, final set to be not less than 30 minutes.

Slow setting cements to be used in all cases, except for submarine work and in places where water and tides interfere with slow setting cements.

Fineness.—Cements to be of such fineness that 95%, by weight, shall pass through a No. 100 sieve, having 10,000 meshes per sq. in.; 80%, by weight, shall pass through a No. 200 sieve having 40,000 meshes per sq. in.

Checking and cracking.—Two cakes of neat cement to be molded on glass. One to be immersed in cold water, after having set hard, and examined from day to day for surface checking and warping. The other, after having set hard, to be immersed in water at 212° F., and allowed to remain in the water at that temperature for 24 to 36 hours. Examination to be made of the pat at the end of that time for constancy of volume and checking. Should the pats become contorted, or show signs of cracking or warping, the cement will be rejected.

Specific gravity.—The specific gravity shall not be less than 3.00.

Tensile strength.—Neat briquettes shall stand a minimum tensile strain per sqare inch without breaking:

12 hours in air and 12 hours in water	200 lbs.
1 day in air and 6 days in water	500 "
1 day in air and 27 days in water	650 "

Sand, mortar briquettes, 3 parts of sand (No. 4 standard crushed quartz) to 1 of neat cement shall stand a minimum tensile strain per square inch without breaking:

1 day in air and 6 days in water	150 lbs.
1 day in air and 27 days in water	250 "

Manner and Method of Testing.

All Portland cement will be tested according to the following manner described:

Sample.—When the sample is received, carefully mix in a suitable vessel to thoroughly distribute the coarser particles and make it more uniform.

1. Setting.—Mix 100 grammes of neat cement with the correct percentage of water, previously ascertained. Mold the same on a piece of glass 4 ins. square, making the centre of the pat about ½ in. in diameter, and drawing the mass down to a fine edge on the glass; the whole pat assuming a circular shape. When the surface of the cement will sustain a weight of ¼ lb. supported on a wire 1-12 in. in diameter without making any impression, the difference between this time and the time of making is the initial set.

Final set.—When the surface of the cement will sustain a weight of 1 lb. on a wire 1-24 in. in diameter without making any impression, the difference between this time and time of making is the final set.

Fineness.—Pass 100 grammes of cement through a No. 100 and No. 200 standard brass gage sieves (containing, respectively, 10,000 and 40,000 meshes to the square inch). The weight of each residue gives the percentage of fineness of the cement passing through these sieves.

Hot and cold water test.—Mold two pats of neat cement as heretofore described under setting. Allow same to set in air (covered with a damp cloth to prevent surface drying) for 24 hours.

Immerse one in cold water, and allow it to remain in water for an indefinite period—for at least seven days—examining it, from time to time, for warping, checking and cracking.

Immerse the other pat in water 212° F., and allow it to remain for 24 hours in the water at the same temperature; at the end of which time remove the pat and examine for disintegration and constancy of volume.

Mixing and gaging.—Never mix more than a sufficient quantity for one mold, when the initial set is under ten minutes, using 150 grammes of neat cement for each mold, with the addition (at one time) of the proper percentage of water previously determined. Mix and knead the cement thoroughly by hand, using rubber gloves as a protection, and afterwards troweling it in order to bring it to a fine edge, and causing it to shed water. After being thus thoroughly worked until the mass is homogenous, proceed to fill the molds, having first wiped the inside with an oily cloth, in order to prevent sticking, and laying them on a flat smooth piece of slate. Press the cement in with the thumbs, being careful to allow no air bubbles in the cement. Having filled all the molds, smooth them off with a spatula or trowel upon which a slight pressure is exerted.

In the case of neat cement, do not turn or move the moulds from the table after the cement is put in, as the under side will present a smooth surface similar to the upper, if a perfectly smooth surface is used to lay the moulds on and the cement has been carefully pressed in. Cover the briquettes with a damp cloth, immediately after molding, in order to prevent rapid surface drying and to cause a uniform set.

For 24 hour neat test, remove filled molds from slab as soon as set and stand on ends without covering of damp cloths, for 12 hours. Then remove briquettes and immerse in water for the balance of the 24 hours.

For 7 or 28 day tests, remove briquettes from molds at the end of 12 hours, and allow them to remain under a damp cloth for the balance of the 24 hours; then immerse in water for 6 days or 27 days. Then break them in a good testing machine, such as Riehle's or Fairbanks'.

Sand briquettes.—In the case of sand briquettes weigh out 600 grammes of sand and 200 grammes of cement, and mix dry in a pan, add half the percentage of water ascertained in the neat test. Mix this mass well on a slate slab, to thoroughly incorporate the sand and cement, using a trowel for this purpose. This complete mixing is very necessary in the case of a finely ground cement. Care should be taken that the mortar does not become too dry during the manipulation; if it does, dip the trowel in water, which will be sufficient to keep it moist. Having thus mixed it well, press it into the molds, previously arranged as in the case of neat cement. Smooth and trowel the top and bottom of the briquettes, turning them carefully for this purpose, in order to bring the moist cement to the surface, thus filling the voids and making both sides of the same degree of smoothness. This will prevent one side from being more absorbent than the other when immersed.

For 7 or 28 day sand mortar test, remove the briquettes from mold at end of 12 hours and place under damp cloths, immersing them in water at the end of 24 hours (the same as in the neat tests for like periods of time) for 6 days or 27 days, respectively, as the requirements may be.

Sand.—Sand used should be standard crushed quartz, No. 4, capable of passing a No. 20 sieve and caught on a No. 30 sieve (sieves, standard brass gage, having 400 meshes and 600 meshes to the square inch, respectively).

Water.—Water used for tempering and gaging, as well as for the immersion of briquettes, should be clear, and between 65° to 70° F.

Notes.—When mixing rapid setting cements care should be taken that the initial set does not take place before molding; if it does, the mass should be rejected. Care should always be taken to keep the briquettes completely submerged in the water while immersed, and make the test as soon as they are removed from the water. Stand the briquettes on end while immersed in the pans, so that the maximum surface will be at all times exposed to the water.

Mark on each briquette a number, same referring in some suitable record book to brand, days of making, tesing, breaking and full tests and properties of cement.

The advantages to be derived from uniform specifications and manner of testing such as advocated are enumerated by Mr. Donaldson as follows:

1. A standard system applicable alike for all departments.
2. Knowledge of the proper and economic use of Portland cements.
3. Higher standards and consequent rejection of inferior brands, due to an accurate system of tests.
4. All cements placed on an equal footing and merits determined.
5. Incentive to the betterment of quality.
6. The fostering of an American industry.

In conclusion, Mr. Donaldson presents some argument for the above specifications which are worth careful consideration. He urges that present specifications are defective in not insisting on fine grinding. The residue on a 200 sieve, he states, is of no more value than so much sand, as it has no setting properties, and in comparing the price of different cements, it should be remembered that it is only the fine portion that is of value; one cement may be nominally more expensive than another and yet be actually the cheaper, on account of its smaller percentage of unground particles. The improvements in grinding machinery during the last few years have made it possible to grind cements finer than formerly, at slight increase of expense, so the engineer need not be deterred from insisting on finely ground cement by reason of extra cost.

Another important point raised by Mr. Donaldson, is the advantage of shipping cements from the works to the place of use, in bags instead of barrels. It is exceedingly common to see in specifications a clause inserted requiring the cements to be shipped in casks; when, if the engineers only knew it, it is better to have it shipped in bags. The cement is thus more perfectly seasoned; it can be more readily and cheaply handled; and the manufacturer can afford to sell it at a materially less figure, as the bags are returnable, and are used over and over again. In other words the purchaser of the cement gets a better article at a less price.

◆

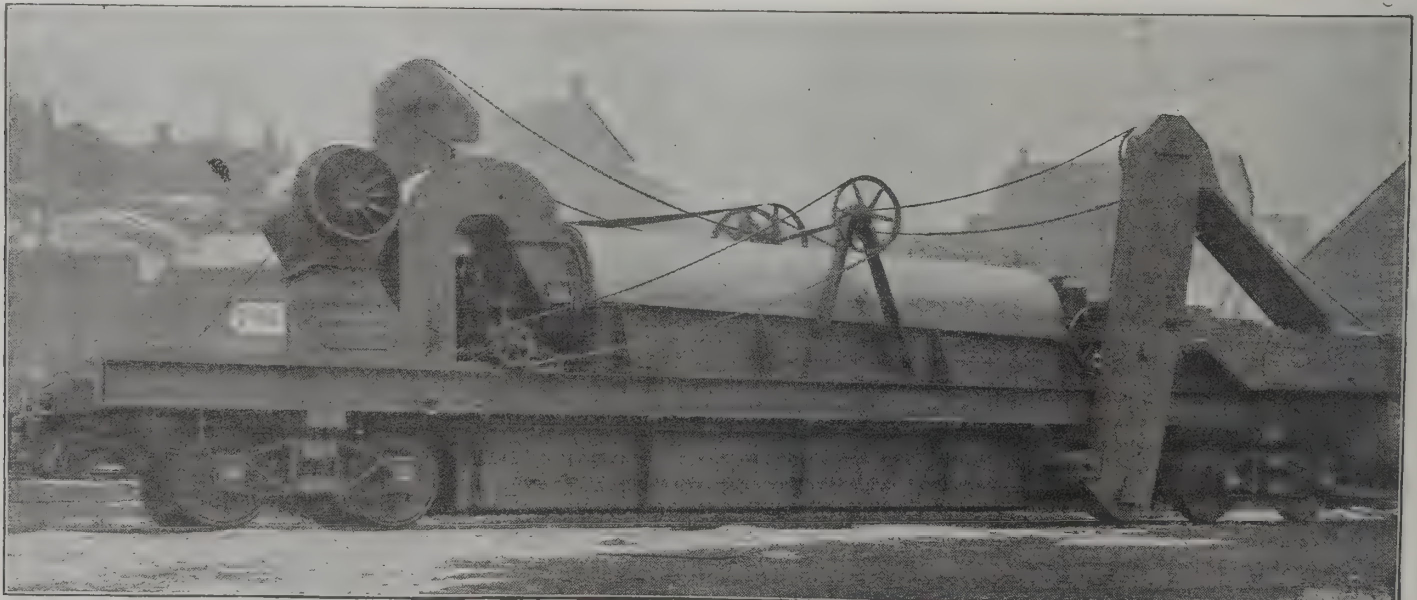
A PORTABLE DRYING AND HEATING PLANT.

We show herewith an invention of much practical interest in many industries. It is a drying and heating apparatus mounted on the trucks of a standard railway car, so as to be easily moved from place to place, and adapted for drying and heating sand, crushed stone, or other materials on a large scale, and with great economy and efficiency. The plant was designed and built by the F. D. Cummer & Son Co., of Cleveland, O., and consists of an all-steel car frame, 48 ft. in length and 9 ft. 3 ins. wide over all. On this is set a Cummer, style A, patent dryer and heater, with a 25 HP. Westinghouse engine and the necessary elevating and power transmitting machinery.

The firebrick about the dryer is so secured, we are informed, as not to be likely to crush or loosen under the shocks and jars experienced on the road, and the lowest point of the dryer has more clearance above the rails than a locomotive pilot. The car has M. C. B. couplers and Westinghouse air brakes, and has been examined and accepted by the railway officials for transportation.

Two elevators are used in connection with the dryer, as shown, one feeding the drier, and one delivering the dried and heated material to the screen or to any point desired. The operation of the apparatus is easily regulated, and the material heated can be delivered dried and uniformly heated to any temperature from 150° to 600° F.

The cut herewith is reproduced from a photograph of a drying plant recently built for a large asphalt paving company. The apparatus shown will dry and heat about ten tons of sand per hour.



PORTABLE DRYING AND HEATING APPARATUS.
Designed and Built by the F. D. Cummer & Son Co., Cleveland, O.

LOW LEVEL BRIDGES IN QUEENSLAND.

Australia is a country famous for its alternations of drought and flood. Water courses which, in the dry season, shrink till they almost disappear, are converted by sudden rains into broad, deep rivers, which subside, however, as quickly as they rise. To carry highways across these streams by bridges at a level above the highest floods is a very expensive task, as high piers or long spans are required and iron or steel bridges are expensive. Moreover, as is well known, the greater part of the country is sparsely inhabited, and the traffic will not warrant great expense in the maintenance of highways.

To meet these conditions, the Australian engineers have in some case adopted what are known as low-level bridge. Instead of building a bridge above high-water mark, they make it high enough, merely to clear the water surface at moderate floods, and permit the higher floods to submerge it entirely, considering it better to suffer the inconvenience of a stoppage of traffic during the short time that these higher floods last than to go to the expense of a high-level bridge.

Of course the low-level bridges are especially designed to resist the force of the current of water when submerged; but, on the other hand, they are not subject to danger by drift piling up against them and forming a dam, as the debris is not carried down a river in considerable quantity until a stage is reached at which a low-level bridge would be submerged.

A paper describing some of these low-level bridges was recently read before the Institution of Civil Engineers, by Mr. A. B. Brady, M. Inst. C. E., of Brisbane, Queensland, and we reprint the substance of it as follows:

Herbert River Bridge, Garloch.

The level of the decking of this bridge is 10 ft. above high water of ordinary spring-tide, or 29 ft. below the highest flood-mark. The bridge has a total length over the abutments of 481 ft. 3 ins.; and consists of 14 spans of 33 ft. each, the clear width of roadway between the curbs being 16 ft.

The piers, 13 in number, together with the abutments and wing-walls, are built of Portland cement concrete composed of one part of cement, three parts of clean sharp river-sand, and six parts of hardstone broken to 2-in. gage. The string-courses under the steel superstructure were formed of a stronger concrete composed of one part of cement, two parts of sand, and three parts of hardstone broken to 1½-in. gage. The pier foundations were laid on rock at depths varying between 4 ft. 6 ins. and 6 ft. below high water, temporary wrought-iron caissons, constructed in sections bolted together having been used. The maximum depth of sand overlying the rock-bottom was 4 ft. 6 ins; and the maximum depth of sinking in the rock 1 ft. 6 ins. Each pier has semi-circular ends with a batter of 1 in 12 above the plinths; the batter of the sides, between the splayed plinth and the underside of string-course, being 1 in 24. All exposed faces of the concrete in the piers and abutments were floated with a mixture of one part of Portland cement to two parts of sand.

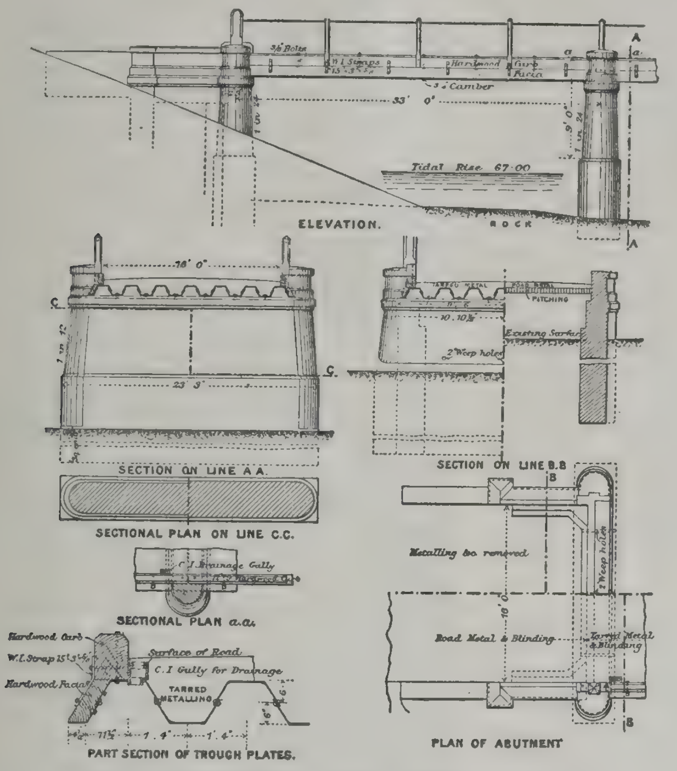

FIG. 1.—THE HERBERT RIVER BRIDGE, GAIRLOCH.

The superstructure or decking of the bridge was formed of mild-steel or trough-plates 12 ins. in depth, weighing 25.82 lbs. per sq. ft. of area covered. The plates were

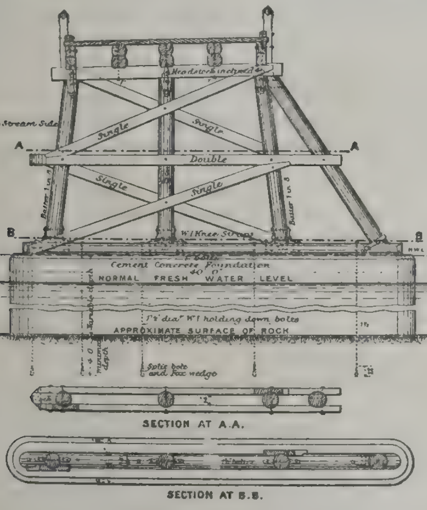

Fig. 3.—The Mary River Bridge, Tiaro.

campered to the extent of ¾ in. at the centre of each span, and the sections riveted together with ⅝-in. rivets at 6-in. pitch throughout. The trough form of superstructure possesses many advantages for short spans, as girders may be entirely dispensed with, and, in the case of low-level bridges, the small depth of the troughs offers but little resistance to the passage of flood-waters during the wet seasons. The whole of the steel-work received three coats of tar. For securing the steel superstructure to the piers and abutments, 1-in. lewis-bolts were fixed in the concrete string-courses, the upper surfaces of which were trowelled smooth and level, to form a uniform bearing for the steel-trough decking. The bolt-holes at one end of each trough were slotted to allow for expansion of the decking.

The road or carriage-way was formed of metalling, broken to 2-in. and 1-in. gages in equal proportions, mixed with boiling coal-tar. The troughs were completely filled with tarred metal, and were covered to a depth of 7 ins. at the crown and 5 ins. at the curbs, being well punned and afterwards rolled and covered with sand. Drainage from the surface of the roadway is provided for by 30 gullies having outlets through holes cut in the trough decking. The curbs are of Moreton Bay ash, 12 ins. by 9 ins., bolted to the steel decking; and the handrailing is of hardwood posts and iron chains easily removable.

The approaches were made in cutting through the sandy formation of the banks, the cutting for the south approach having a maximum depth of 17 ft. The slopes were faced with bricks laid in cement; and concrete water tables were constructed at the foot of the slopes.

During the construction of this bridge exceptionally bad weather was experienced; and two of the highest floods known in the locality occurred, resulting in considerable delays, loss of plant and materials, and damage to the approaches. In April, 1894, two and a half years after the bridge was opened for traffic, the Herbert river was visited by the most disastrous flood that has ever been recorded in the district, considerable damage occurring to the tarred metal or asphalt roadway on the bridge, necessitating its entire renewal. In repairing the roadway the quantity of tarred metalling, which, on account of its depth in the troughs of the decking, required a long time to set sufficiently hard for traffic, was reduced by filling the troughs to a depth of 12 ins., and forming a surface over the decking, with Portland-cement concrete, upon which tarred metalling or asphalt was laid to a depth of 6 ins., and reduced by rolling to 5 ins. The concrete was composed of one part of Portland cement, one part of river sand, and six parts of stones from the river of 2-in., 1-in. and ¼-in. gages in equal quantities. The asphalt was formed of broken river-metal of 2-in. and 1-in. gages in equal quantities, mixed with ¼-in. screened river-gravel, in the ratio of six parts of stone to one of screened gravel. After being thoroughly dried, heated, and well mixed with the required quantity of boiling coal-tar, it was stacked to allow the superfluous tar to drain off, and then laid on the surface of the concrete and rammed and rolled. The surface was finished with 1 in. of tarred sand and screenings, composed of four parts of coarse sand and two parts of fine gravel screened, dried, heated and mixed with boiling coal-tar as before. After finishing, the entire surface was covered with clean sharp river-sand to a depth of ½ in.; and, to give sufficient time for the asphalt to harden, a month was allowed to elapse before the bridge was reopened for traffic.

The contract for the construction of this bridge was let in January, 1890, and it was completed and opened for traffic on the 4th of November, 1891, the total cost of the bridge and approaches amounting to £7,737 16s. 7d. The cost of the bridge, exclusive of approaches, amounted to £5,704 4s. 0d., or £11 17s. 0d. (nearly $60) per lin. ft. The cost of the concrete and asphalt work, together with some other necessary repairs, amounted to £684; the total cost of the bridge being thus increased to £13 3s. 6d. per lin. ft. ($66).

Balonne River Bridge. St. George.

This bridge is wholly of bloodwood (Eucalyptus corymbosa), and consists of twelve spans of 35 ft. each, with two end-spans of 28 ft. each; the total length over the decking being 481 ft., and the width of roadway between the curbs, 18 ft. The height of the bridge above the lowest or dry weather level of the river is 15 ft., the highest flood having reached a level of 16 ft.

Each pier has four piles spaced at 6-ft. 2-in. centers at the level of the headstock; the two outer piles having a batter of 1 in 8, and the two intermediate piles being planted vertically. The diameter of the piles, exclusive of sapwood, is 17 ins., the butt-end being placed downwards in every case. Each of the outer or battered piles was lewised to the rock-bed of the river, each hole being cut to a depth of 5 ft., the dimensions at the bottom being 46 ins. long by 14 ins. wide. The sides and one end were cut vertically, and the opposite end tapered so as to reduce the length of the hole at the surface to 26 ins. The sides and ends of each hole were carefully rough-tooled to exact lines; and properly-shaped wedges of seasoned bloodwood were then inserted, and made to bear evenly against the rock. The feet of the piles were squared for a length of 6 ft. 6 ins.; they were then inserted in position between the wedges, and firmly driven home, the whole being securely bolted together above the surface of the rock. The wedges and the feet of the piles before being fixed were twice coated with Stockholm tar; and, after fixing, the interstices were completely filled in with strong-cement grout. The two intermediate piles in each pier, and also the abutment piles, were planted in rock, the holes for which, 24 ins. in diameter, were jumped or excavated to a depth of 4 ft. The feet of the piles were freed from sapwood, and twice coated with Stockholm tar; they were then planted in the rock, the space round each pile being completely filled with cement concrete. The sites of eight of the twelve piers were above the summer level of the river, but the first four piers from the St. George side of the river were in water, necessitating the provision of a cofferdam for each pier, to admit of the holes in the rock being cut without the aid of divers. Each pier was capped with a 12-in. by

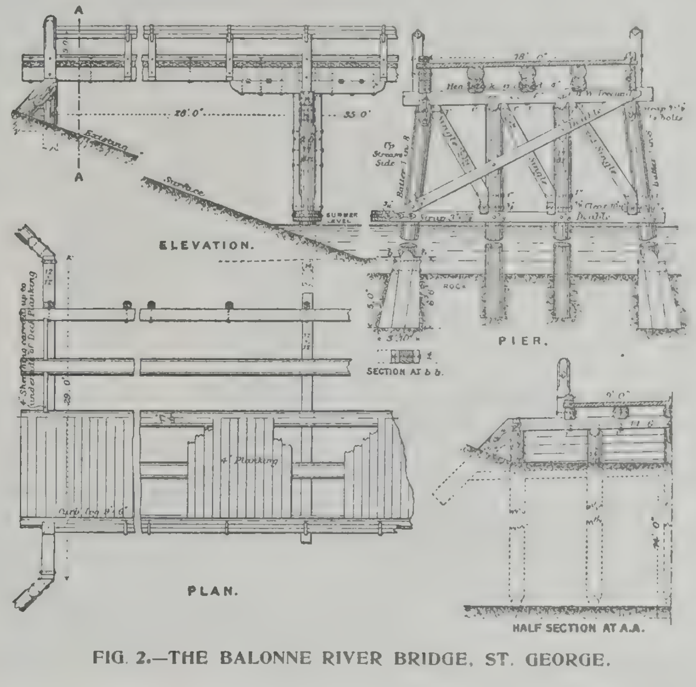

FIG. 2.—THE BALONNE RIVER BRIDGE, ST. GEORGE.

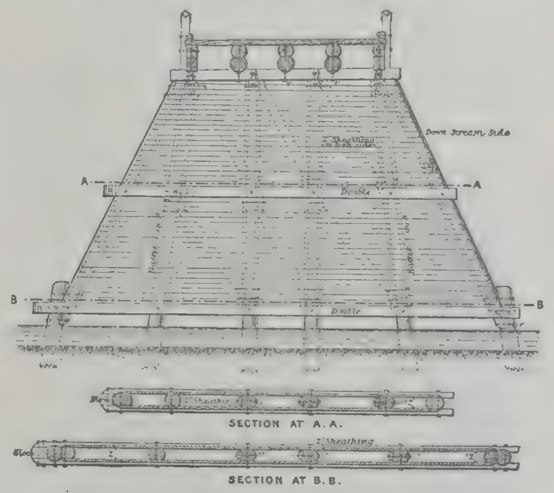

Fig. 4.—The Mary River Bridge, Gympie.

12-in. headstock inclined 4 ins. in its length towards the upstream side of the bridge, and provided with double 10-in. by 6-in. walings above water or rock-level, three 10-in. by 12-in. struts between the piles, and double 10-in. by 6-in. diagonal braces. The walling and braces were cogged on to the piles, and the whole well bolted together. The upstream ends of each pair of walings were shaped and blocked solid to form a cut-water, and were well secured with wrought iron straps and bolts.

Each span consists of five girders or stringers scarf-jointed over the piers, and carried upon single corbels, 14 ft. long, through which the girders were bolted. The corbels were cogged on to the pier headstocks; and, in addition to being bolted, the girders were keyed to the corbels with well-seasoned wedge-keys tightly driven, working 3 ins. square, and having a 4-in. projection on each side for tightening. The superstructure is secured to the piers by through-bolts and anchor-bolts. The decking consists of 9-in. by 4-in. planks laid transversely over the girders in one length from side to side, and spiked down with 8-in. by ½-in. spikes. The outer girders and corbels exposed to view are of hewn timber 14 ins. by 12 ins.: the inner girders and corbels being of round timber 17 ins. in diameter, exclusive of sapwood, adzed flat to a thickness of 14 ins. over all bearings and for the planks of the decking. The entire superstructure is built with an inclination of 4 ins. toward the upstream side to prevent lodgment of driftwood under the bridge decking in time of flood. The abutments were sheathed at the back of the piles with 4-in. planking, carried also along the wings of the abutments. The curbs measure 9 ins. by 6 ins., and are rounded on one edge and bolted through the decking and girders; the curb on the upstream or lower side of the bridge being raised 1½ in. to allow for drainage from the surface of the decking. The handrails, 6 ins. square, are placed diagonally on 9-in. by 6-in. intermediate posts, and 9-in. by 9-in. main posts over the piers, terminating at the ends of the bridge in 12-in. by 12-in. guard-posts securely fixed to the girders of the end spans and tenoned into the abutment headstocks. The handrailing is only 3 ft. above the decking, and of exceptional strength, without intermediate rails and wires, so as to offer as little resistance as possible during floods, and to enable it to withstand the pressure due to the accumulation of flood debris. Strong permanent handrails are to be preferred to movable handrails, which are troublesome and expensive, and their removal at the vital moment is often neglected.

The whole of the timber-work received three coats of oxide paint, with the exception of the decking, which was covered with three coats of Stockholm tar. Since it was opened for traffic, this bridge has been several times submerged by floods without sustaining injury.

The construction of the bridge was commenced in October, 1890, and it was opened for traffic in June, 1892, after many troublesome delays in consequence of wet weather and floods. The total cost amounted to £4,467 16s. 4d., inclusive of approaches, which alone cost £419 10s. 0d., the cost of the bridge per lin. ft. amounting to £8 8s. 4d.

The author also describes two bridges across the Mary River. We reproduce the cuts illustrating them, as they show sufficiently the features of principal interest in their construction.

A DIRECT-ACTING STEAM PILE HAMMER.

We illustrate this week a steam pile hammer made by the Vulcan Iron Works, of Chicago, which is a modification of the steam hammer for this purpose invented in England in 1841 by James Nasmyth. The apparatus is slung between the leaders of a pile driver and has its whole weight resting on the pile, the pile cap and cylinder casting being connected by four turned rods, upon which the hammer head slides. The general design of the apparatus is shown in Fig. 1.

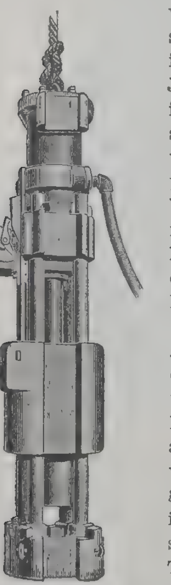

Fig. 1.—View of Vulcan-Nasmyth Steam Pile Hammer.

In the detail drawing, Fig. 2, A is the hammer head, bored out for the four rod guides B, the lower or striking end of the head being of smaller diameter and passing through the cap D, which rests on the pile. The guide rods attach the cylinder C to the cap D, and are secured by keys at each end. The hammer head is attached to the rod of the piston E. The oscillating valve F works within a cylindrical chamber formed in the steam chest, this chamber being provided with three ports; port G opens into the lower end of the cylinder, H is the steam and I the exhaust port, steam being admitted from a flexible pipe attached at J. The spindle of valve F carries at one end (outside the steam chest), the arms or tappets K, L, which engage with lugs on the rod M attached to and moving in connection with the hammer head. These lugs are not in the same vertical plane, only one lug engaging with each of the tappets. At the end of the upstroke of the cylinder and hammer head the lower lug will have passed the tappet L without striking it, but will strike the tappet K, moving the valve so as to open communication between ports G and I, and allow steam to exhaust from below the piston. At the end of the downstroke the upper lug will pass the tappet K and strike the tappet L, moving the valve to the left, so as to open communication between ports G and H for steam admission under the piston.

In sinking test piles for the foundations of the Chicago Public Library (Engineering News, July 6, 1893), a Vulcan-Nasmyth hammer was used, weighing 4,500 lbs., having a stroke of 42 ins., and striking 54 blows per minute. The last 20 ft. were driven with a follower of oak, requiring 48 to 64 blows for the last foot, and as the ratio of blows without follower to blows with follower is as 1 to 2, it was estimated that only 24 to 32 blows would have been required if the last foot had been driven with the hammer striking the pile direct. In the same soil it required about 16 blows of a 3,000-lb. drop hammer falling 30 ft. to drive a pile the last foot, using a follower, and 32 to 36 blows of the same drop hammer falling 15 ft., also using a follower.

◆

UNIFORM METHODS OF TESTING IRON AND STEEL.

Several years ago a committee was appointed by the American Society of Civil Engineers to report upon uniform methods of testing the material used in metallic structures. The committee has made, we believe, one or two preliminary reports, and its final report has just been presented at the annual convention in San Francisco. An abstract, summarizing the recommendations of the committee was prepared by Mr. Henry B. Seaman, 40 Wall St., New York city, a member of the committee, who has had it printed for convenient reference, and will mail copies to those desiring them. We reprint this summary in full as follows:

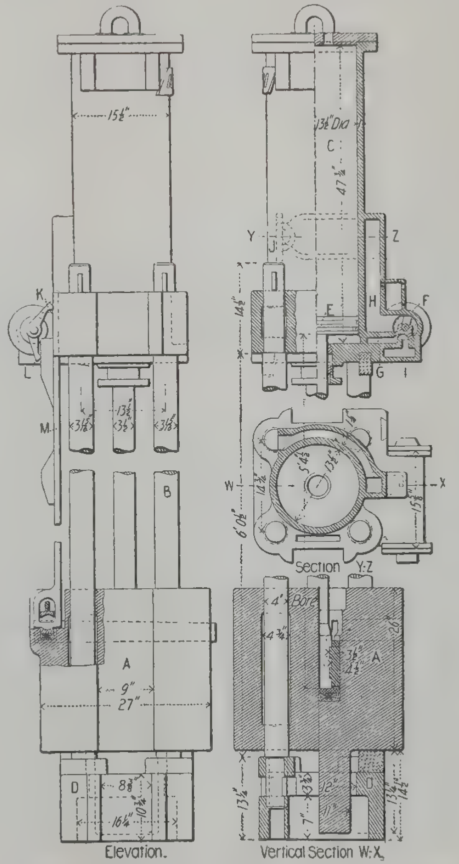

Fig. 2.—Details of Vulcan Nasmyth Steam Pile Hammer; Vulcan Iron Works, Makers.

Cast Iron.

We recommend the transverse tests of a specimen 2 × 1 ins. in section and 27 ins. long, resting flatwise on dull knife-edge supports 24 ins. apart, c. to c., with an applied weight of 2,000 lbs. or more, midway between them. The specimen, if of satisfactory strength when cast under the same circumstances as those which attend the casting of the full-sized piece, must carry at least the minimum weight named above, and exhibit when broken the fracture of gray iron of good quality. Failure shall be produced in not less than two minutes nor more than five minutes from application of the first load, and the bar must show a center deflection before breaking of at least 3-16 in., and must indicate a good quality of gray iron.

Wrought Iron.

The committee recommends that the expression "elastic limit" be confined in its use to its original meaning, since its more general adoption leads to ambiguity and to useless discussion and dissension. The usual methods of testing indicate the first strength or "yield point" of the material, and in order to avoid the objections already mentioned, the committee has confined itself to the expression "yield point" when applied to practical testing. The "drop of beam" is considered sufficiently accurate to determine the "yield point," but the increased accuracy of autographic records, or use of instruments of precision is recommended.

Experimental investigations show that the relative dimensions of a test piece become of little practical consequence if the gaged length exceeds about four times the greatest diameter of the specimen. It is therefore recommended that a minimum gaged length of 8 ins. be used for the general practice of testing specimens, with a distance of not less than 12 ins. between shoulders of the specimen, or between the jaws of the testing machine. Under these conditions, however, it is understood that the gaged length shall in no case be less than four times the greatest diameter of the test piece, and that the minimum thickness shall be ¼ in.; also that the sectional area of test piece shall not be less than ½ sq. in. In obtaining the final elongation, the curves of reduction each side of the point of fracture should be included in the measured length.

In testing it is recommended that the load be applied continuously and at a rate as nearly as practicable of 4,000 to 5,000 lbs. per sq. in. per minute below the yield point, and of 7,000 to 8,000 lbs above the yield point.

It is recommended that the ordinary bending test be continued, and that it be made rapidly with pressure, rather than with blows of a hammer, as the results are thereby more comparable. The nicked bending or fracture test, however, does not show any essential property of the material which would not be disclosed by the tests already mentioned, and hence its adoption is not recommended.

For the requirements of wrought iron with the tests outlined, the following are recommended:

	Bars, per sq. in.	Tension; plate, angle and other shapes.	Compression; plate, angle and other shapes.	Web plates.
Yield point, lbs. (1=1,000)	26	26	26	26
Ultimate, lbs. (1=1,000)	50	48	48	46
Elongation in 8 ins., %	20	15	12	8
Reduction of area, %	30	20	16	12

Specimens should bend cold 90° without fracture, with inner radius of bending not exceeding twice the thickness of the test piece for bar iron, nor three times that thickness for plate and shape iron.

Rivet iron must be soft and tough, and pieces of the full diameter of the rivet must be capable of bending cold until their sides are in close contact without showing signs of fracture.

Rolled Steel.

The methods of testing wrought iron may, in general, be applied to rolled steel. In addition to these, however, the quenching test may be used to advantage, by which a specimen heated to cherry red is to be quenched in water of 82° F., and then tested as usual.

The drifting test is not recommended as a requirement for quality, and the annealing test is recommended only for full-size eye-bars.

For the requirements of rolled steel, it is recommended that a mean ultimate resistance be specified for each grade of steel, and that the ultimate resistance of the test specimen should not vary more than 4,000 lbs. per sq. in. either way from the resistance specified. It is also recommended that the yield point, the elongation and the reduction of area each be a function of the ultimate strength found in the test specimen.

The following requirements are recommended for the various grades of steel:

Ultimate Strength per Square Inch.

Low steel	60,000 lbs.	± 4,000
Medium steel	65,000 "	± 4,000
High steel	70,000 "	± 4,000

Yield point = 55% of the ultimate resistance of specimen.

$$\text{Per cent elongation in 8 ins.} = \frac{1{,}500{,}000}{\text{Ultimate}}$$

$$\text{Per cent reduction of area} = \frac{2{,}800{,}000}{\text{Ultimate}}$$

Rivet steel when heated to a low cherry red and quenched in water at 82° F. must bend to close contact without sign of fracture. Specimens of low steel when treated and tested in the same manner must stand bending 180° to a curve, whose inner radius is equal to the thickness of the specimen without sign of fracture. Specimens of medium steel, as cut from bars or plates and without quenching, must stand bending 180° to an inner radius of 1½ times the thickness of the specimen without sign of fracture; while those of high steel, also without quenching, must stand bending 180° to a radius of twice the thickness of the specimen without sign of fracture.

Steel Castings.

In steel castings the tension test is recommended, with the following requirements:

Ultimate	65,000 lbs. per sq. in.
Yield point..	35,000 " " "

Elongation in 8 ins. = 15%.
Contraction = 25%.

Respectfully submitted, James G. Dagron, Robert W. Hunt, Henry B. Seaman, William H. Burr.

TESTS OF THE EFFICIENCY OF AN INJECTOR

By Karl Andrén.

The following results were obtained from a series of experiments upon an injector manufactured by the Penberthy Injector Co., of Detroit, Mich. and listed as No. CC in their catalogue for 1895.

Four series of tests were made under the following conditions:

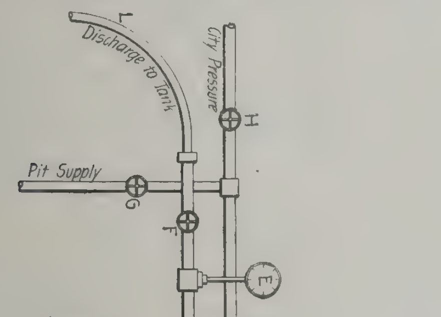
I. Greatest discharge, under constant steam pressure and suction head, against varying pressures in the discharge pipe, the water being supplied to the injector at the city pressure, 50 lbs.

II. Least discharge, under the same conditions.

III. Greatest discharge, under constant steam pressure and with a lift of the supply water of 9 ft. 10 ins., against varying pressures in the discharge pipe.

IV. Least discharge, under conditions of the third series. The accompanying sketch explains the arrangement of piping used in the tests.

A represents a separator, made of 4-in. steam pipe, and having cast-iron caps at the top and bottom, as shown. B is the steam pipe from the boiler: This passes centrally through the top cap of the separator and extends downward about half way between the two caps. This pipe is open at its lower end. The steam leaves the separator near the top cap and is carried to the injector P. E is a pressure gage in the discharge pipe and F is a throttling valve, by means of which varying discharge pressures may be obtained and registered on E. G is a globe valve in the lifting pipe, connected to the pit supply. This valve was closed, except in the lifting tests. H is a globe valve in the city water pipe. This valve was wide open during all tests on greatest discharge when city pressure was used. In all the tests the injector steam valve I was wide open, as recommended by the manufacturers. Preparatory to all tests on least discharge with city pressure, the limiting action of the injector was determined by alternate manipulations of the valves H and F, until the desired discharge pressure was noted at that point, directly after which the injector would fail to work without leaking at the overflow. In all lifting tests the globe valve H was closed. During tests for greatest discharge with suction the valve G was opened wide, the desired discharge pressure being regulated by means of the throttling valve F. In the lifting tests for least discharge, the valve G was operated in connection with the throttling valve F in a similar manner to that before described in the least discharge at city pressure. J and K are two accurate centigrade thermometers, set into oil cups in the suction and discharge pipes respectively. To the end of the discharge pipe is coupled a piece of rubber hose L. This leads to a wooden tank set on Fairbanks' scales, not shown in the drawing. The scale arm weight was adjusted to balance the tank when empty, and 350 lbs. in weights were placed on the scale pan. A boiler steam gage was also near at hand so that all readings were easily obtained from a stand near the injector. The time in seconds was noted for each discharge of 350 lbs.

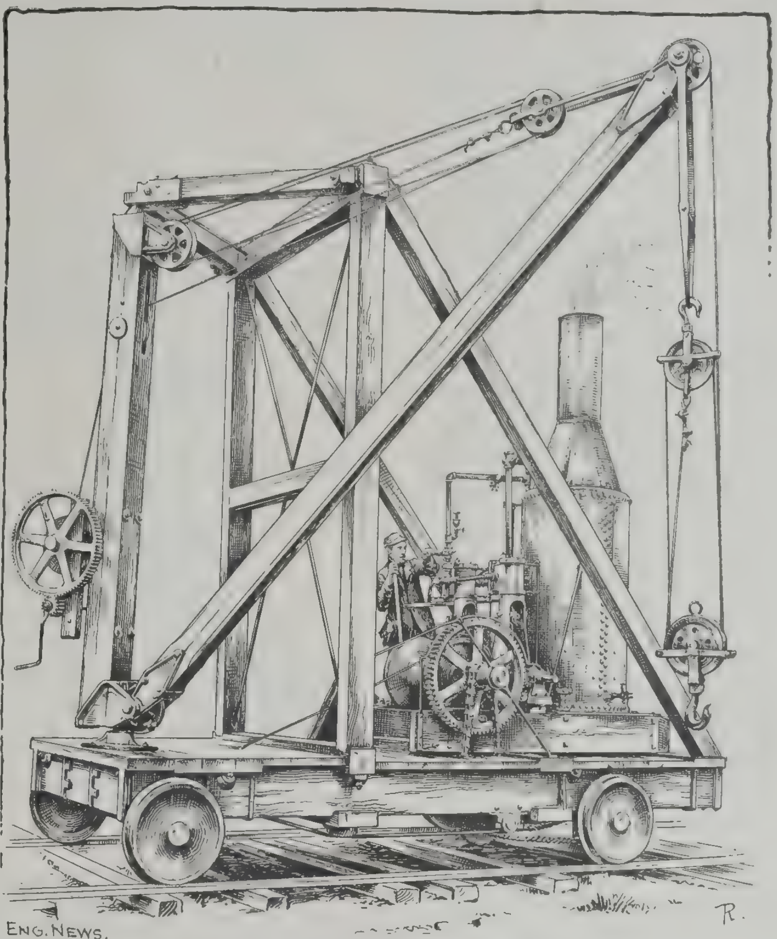


Arrangement of Apparatus for Injector Test.

The diameter of the injector combining tube was determined by the micrometer measurement of a soft wooden taper rod, which was accurately fitted to the smallest section of the tube. It was found to be 0.215 in.

Explanation of the symbols used in the equations:

W = Weight in lbs. of water discharged during the test.
S = Weight in lbs. of steam used during the test.
L = Total heat of the steam.
t_3 = Temperature in degrees Fahrenheit of the suction water.
t_4 = Temperature in degrees Fahrenheit of the discharge water.
q_3 = Heat of the liquid corresponding to the temperature t_3.
q_4 = Heat of the liquid corresponding to the temperature t_4.
350 = Weight in lbs. of the water + steam (condensed) discharged = capacity of the weighing tank during each test = $W + S$.



AN ECONOMICAL TRAVELING DERRICK CAR.

All the results were obtained by substitution in the following formula, which is adapted from the equation (219) in Prof. Peabody's "Thermodynamics of the Steam Engine."

$$W(q_4 - q_3) + (W + S)\frac{AV^2}{2g} = S(L - q_4)$$

But since $S = 350 - W$

$$W(q_4 - q_3 + L - q_4) = 350(L - q_4) - 350\frac{AV^2}{2g}$$

and hence

$$W = \frac{350\left(L - q_4 - \frac{Av^2}{2g}\right)}{L - q_3} = \frac{350\,(L - q_4)}{L - q_3}\text{(practically).}$$

The following deductions can be made from the accompanying tabular results of tests:

Tests of the Efficiency of a Penberthy Injector.

I. Tests with maximum discharge. Water supplied to injector under pressure of 50 lbs per sq. in.

Discharge head lbs. per sq. in.	Average Steam pressure (gage) lbs.	Temperature (Deg. F.) of		Discharge gals., per hour.	Lbs. of water pumped per 1 lb. steam.
		Suction.	Disch'g.

70	70	53.6	179.6	271	8.15
80	70.5	53.6	163.4	315	9.50
90	70	53.6	158	336	10.04
100	Injector leaked at overflow.				
III. Tests with maximum discharge. Injector working with suction lift of 9 ft. 10 ins.					
20	75	72.5	149	474	13.85
30	72	64.4	137.3	486	14.70
40	71.5	61.7	134.6	491	14.74
50	70.5	60.8	132.8	491	14.94
60	71	67.1	140.9	485	14.49
70	71	67.1	140.9	488	14.49
80	70	68	145.4	459	13.62
90	Injector leaked at overflow.				
IV. Tests with minimum discharge. Injector working with suction lift of 9 ft. 10 ins.					
20	70.5	68.9	190.4	281	8.56
30	70	63.5	185	281	8.56
40	71	62.6	185	281	8.33
50	70.5	60.8	181.4	281	8.89
60	71	59	179.6	286	8.51
70	71	59	170.6	306	9.28
80	71	65.3	165.2	344.6	10.43
90	Injector leaked at overflow.				

1. Since the life of a boiler is greatly increased when fed with hot water, a larger injector than that size, which, when working at its maximum capacity, is just sufficient to feed the boiler, should be used. The considerable increase in the temperatures of the feed water, when the injector is working at least discharge, warrants this suggestion.

2. In case the injector is to be used as a pump, in which case it would generally be regulated so as to give the greatest discharge, it is seen that it is much more efficient against high heads than againtst the lower heads.

3. A comparison of II. and IV. shows that the discharge with a lift of 9 ft. 10 in. is greater than the corresponding discharge when the city pressure was used, while the final temperatures of each set vary only slightly. This is not true for the maximum discharges of each set.

4. In general, the maximum discharge of each class is decreased as the pressure head is increased, while the corresponding temperature of the discharge is proportionally greater. But a comparison of the minimum discharges of each class shows that the temperature of each discharge decreases as the pressure head is increased, while the discharge per hour is materially increased.

* * *

A TRAVELING DERRICK CAR.

The accompanying cut represents a simple and economical derrick, mounted on a car fitted with propelling gear, and intended for use in quarries and similar places, and in the construction of buildings, foundations, sewers, etc., where fixed derricks have many disadvantages. The car, derrick-post, boom and supporting frame are of timber, and on the car are a two-cylinder hoisting engine and a vertical boiler. A sprocket chain from the main shaft drives a countershaft under the car platform, while another chain, running from a smaller wheel on the countershaft drives a sprocket wheel keyed to the rear axle. The derrick has the ordinary cast-iron shoes and fittings, wire rope falls, and wrought-iron blocks and large sheaves. The car is 16 ft. long, with wheels set to 8 ft. gage of track, and it will work on a grade of 2%, with maximum load. The mast is 12 ft. high, and the boom 18 ft. long, the latter swinging through an arc of 270°. The weight is about 15,000 lbs. This machine is manufactured by the John F. Byers Machine Co., of Ravenna, O., It should meet the wants of a large number of manufacturers and others who could use a traveling crane to advantage in loading and unloading goods, machinery, etc., but cannot afford the expenditure necessary for an all-metal machine.

Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The advantages and disadvantages of the head house or "dead end" plan for the arrangement of railway stations are now under discussion in connection with the proposed new union station for Omaha, Neb. The present principal station is on the outskirts of the town, and a new one was proposed on practically the same site, but though work was commenced it does not seem probable that it will be carried to completion, as there is a strong movement in favor of a new and more central location, and accommodating other railways besides those using the present main station. This would be a terminal station, with a head house at the end of the train shed. Through trains would either have to head in, and then put out in a reversed position, a fresh engine being attached to what was the rear of the train; or else such trains must run past the station and then back in, pulling out again without being reversed. The daily papers appear to be decidedly in favor of a station on the new site, and the great terminal stations at Philadelphia and St. Louis are pointed to as examples of "head-house" stations used by through trains. It should be noted, however, that many through trains of the Pennsylvania R. R. do not now enter the Broad St. terminal station at Philadelphia, but pass by that city by a cut-off built for this purpose. On those through trains that do enter there is more or less inconvenience caused by the reversal of position and the necessity of reversing all the seats of the cars. A similar arrangement also used to exist on the Baltimore & Ohio R. R. at Baltimore, and the delays and inconveniences due to this arrangement were among the reasons for building the Belt Line tunnel, giving trains a through station. The question is largely one of traffic conditions. If there are many through trains, it may be advisable to so locate and arrange the station as to provide through tracks, but if the traffic is mainly terminal the head-house plan may be the best. The great terminal stations of the Pennsylvania R. R. and the Philadelphia & Reading R. R. in Philadelphia, appear to be open to objection in this respect, but the Grand Central station, in New York, being purely a terminal station, there is no need for considering any provision for through traffic. As to running past the station and then backing in, so as to avoid reversal, such a plan is very likely to be found inconvenient in many ways, especially as the traffic increases. In fact, we know of one good sized city in England where this arrangement became so troublesome that the entire terminal plan was changed recently, involving great expense, in order to facilitate the train movements. In view of the amount of through traffic at such a place as Omaha, it seems to be eminently desirable to provide through tracks, and not tie up the whole system by a head-house plan, and there should be little difficulty in doing this.

◆

We occasionally receive letters in which the writers complain that we devote too little space to this or that or the other special department of engineering, in which they are especially interested; and say that they care nothing about any engineering literature aside from that which bears upon the work in which they are engaged. In conversation, too, with young engineers, and sometimes with older ones, we hear them too frequently say—sometimes even with a sort of pride—that they read nothing in engineering literature except what bears directly on their chosen specialty.

This mistake, as we believe it to be, is so serious in its results to the one who makes it, that we have thought it worth while to call attention to it here for the special benefit of any of our readers who may be cherishing some such erroneous ideas respecting the way to succeed in professional life. It is true, that specialization is a necessity at the present day; a man must take up some one subject in the field of engineering and completely master it if he would succeed; but if he allows this subject to absorb his attention to the neglect of all other departments of his profession, he cannot aspire to the highest positions, and it is often the case that a man with the broader talents, gained by a wider study of his profession, will outstrip him in preferment even in his chosen specialty.

The fact is that everybody instinctively distrusts the judgment of the man with one idea, or the man with a hobby; and judgment, it is to be remembered, is the greatest quality a professional man can possess. The young engineer, who, when he picks up an engineering journal or buys a book, reads only that which bears directly upon the particular line of work in which he is engaged, is deliberately narrowing his judgment and unfitting himself for the largest sphere of usefulness.

From another point of view, too, this policy of turning all one's energy in a single channel is a mistaken one. No man knows, and least of all the engineer, what he may be doing a year—five years—ten years hence. Changes come rapidly in the profession. A score of years ago many engineers were devoting themselves to railway construction as if their lives were to be spent in that work; but when the practical cessation of railway construction came, a half-dozen years ago, every one of them grasped eagerly at any knowledge or abilities he possessed that could be put to use in other fields of engineering. Alexander Lyman Holley wrote when a young man: "If there is anything certain in this world, it is, that I will never do anything permanently for a living but just this one thing, namely, build locomotives." And not only was he never engaged in a locomotive works more than a few short months after that time, but he won his fame in the field of metallurgical engineering.

The engineer of the present day is fortunate in having available a great storehouse of information in the technical journals and proceedings of technical societies, of which the engineer of early days knew nothing, and which were comparatively unimportant no more than a score of years ago. The engineer nowadays who gets in a rut or remains in ignorance of what advancement is being made in other departments of his profession, does so from choice and not from necessity; and cannot with justice complain if other men, more wide-awake, enthusiastic and up-to-date, outstrip him in the race.

◆

The terrible railway wreck at Logan, Ia., with 31 deaths resulting, which is recorded this week, is the most serious disaster due to the system of operating trains by dispatchers that has been recorded in a long time. According to the best information available, the accident was due to the engineer of the excursion train which was wrecked leaving a station either without orders or in disobedience to orders to await the passage of a fast freight. It is of no use to lay the blame upon the engineer. No one supposes that his disobedience was wilful; no one can say what freak of forgetfulness caused him to make his fatal error. The emphatic lesson of all accidents of this class is that, in order to make men obey orders when the consequence of a failure to obey may be so disastrous, something more than written instructions are needed. Experience teaches that men are far less likely to disobey the instruction of a monitor which is constantly visible before their eyes like a semaphore or a train staff than they are the written message on a train order blank.

◆

The Logan accident and the other serious accident at Altenheim, Ill., make a total of 36 deaths for the week due to excursion trains. In both these accidents it is altogether probable that the fact that the train was an extra was directly responsible for the disaster. The switching engine crew which left the switch open that caused the wreck at Altenheim would probably not have made such a blunder had the train been a regular one which they were accustomed to expect. The engineer of the train wrecked at Logan would have been far less likely to have blundered had he been accustomed to meeting the fast freight every day. Excursion trains are doubtless a necessity; but managers and superintendents should realize the extra hazard that attends their running and put in operation every possible safeguard to protect them.

THE NEEDS AND POSSIBILITIES OF HARBOR IMPROVEMENT AT CHICAGO.

The decadence of the Chicago harbor, or more accurately the growing inadequacy of the Chicago River, to supply harbor facilities to the vessels entering and leaving that port, has from time to time received quite general discussion from the shipping interests of the Great Lakes, and especially from the vessel owners and merchants of Chicago itself. For some years the fact has been gradually forcing itself upon Chicago lake shippers that the city has outgrown its present harbor facilities, and the knowledge has occasioned brief comment in the daily papers and a few discussions of more thoughtful character. Little attempt at general concerted action to improve things has resulted, however, and this inactivity has proved a serious set-back to the Chicago River interests since it has enabled an adjacent harbor to gain considerable prestige, and the apparent favor of the Federal Government as the best, and in fact the only practicable, deep water harbor for Chicago. Whether the injury is to be a permanent one or not, depends very much upon whether a broad and far-sighted solution is sought of the problems involved and upon the energetic action of those having the greatest interest at stake in Chicago's lake commerce. Great engineering and commercial questions are involved, and some space may well be devoted here to a preliminary consideration of the more important of these.

Most engineers outside of Chicago, and probably not a few within that city, are largely ignorant of the straits to which the old Chicago River has come. A prominent daily paper of Chicago recently said in connection with a long discussion of this subject:

> Chicago's supremacy as a shipping center is seriously threatened. In fact the shipping interests do not hesitate to declare that the scepter has passed from the Chicago River; and that were it not for the adjacent Calumet River, the city marine trade would be doomed. The Chicago River, as it exists to-day, is a relic of a glorious and prosperous past. It can accommodate only the second and third class fleets, and is unknown to the modern magnificent lake steamships.

Despite its somewhat turgid rhetoric, this statement is deserving of credence; for if one turns to the reports of the U. S. Government engineer in charge of Chicago harbor for the past few years, substantially the same assertions are found. Indeed, in his latest report, that officer strongly advocates the development by the government of the Calumet River harbor, largely upon the argument that the Chicago River is incapable of accommodating modern lake vessels and affords only limited opportunities for improvement. The advisability of such a policy will be considered further on; but for the present the single fact to be noted is that the expert opinion of the government engineer tallies with that of the newspapers, namely, that the Chicago River is inadequate to the demands for harbor facilities.

The reason of this inadequacy, as hinted above, is the growth in the size of vessels conducting lake commerce. The Chicago River is a narrow, crooked and unutterably foul stream, having a maximum navigable depth of about 14 ft. For the lumber schooner and fourth-class barge such accommodations are reasonably sufficient; but the day of these vessels is past on the Great Lakes. The modern lake steamer has a draft of from 16 ft. to 20 ft., and a net tonnage of from 2,000 to 3,500 tons. Indeed, in many vessels this tonnage is exceeded, and the tendency is every year toward larger rather than smaller vessels. The result is obvious. Either the harbor facilities of Chicago must be improved, or adjacent ports will gradually attract the shipping which naturally belongs to that city. Already, as a matter of fact, the Calumet harbor at South Chicago is drawing the business of the large vessels.

The questions which arise on this showing are these: (1) Is the importance of the Chicago River's lake traffic great enough to warrant any great and costly effort to accommodate and maintain it? (2) If it is sufficiently great, what is the best method of accomplishing the result desired? Evidently the second question is the more difficult, for it involves considerations of engineering, cost and expediency as well as considerations of commercial policy.

Let us consider briefly the question as to the importance of Chicago's lake commerce. According to the report of the Chicago Board of Trade for 1895, the following is the number and tonnage of vessels arriving and clearing at Chicago harbor for each of the past six years:

	Arrivals.		Clearances.	
Calndr. year.	No. vessels.	Tonnage.	No. vessels.	Tonnage.
1890	10,507	5,138,253	10,547	5,150,665
1891	10,224	5,524,852	10,294	5,506,700
1892	10,556	2,966,626	10,567	5,968,337
1893	8,754	5,456,037	8,789	5,449,470
1894	8,259	5,181,260	8,329	5,211,160
1895	9,212	6,329,702	9,363	6,392,497

These figures cover all vessels arriving and clearing at the "Chicago District," comprising the three ports of Chicago, South Chicago and Michigan City. The traffic of each of these three ports in 1895 was:

	Arrivals.		Clearances.	
Port.	No.vessels.	Tonnage.	No.vessels.	Tonnage.
Chicago	7,637	4,602,508	7,687	4,585,834
South Chicago..	1,404	1,682,003	1,504	1,760,838
Michigan City..	171	45,191	172	45,825

That is 72.2% of the total tonnage entered and cleared from Chicago harbor proper.

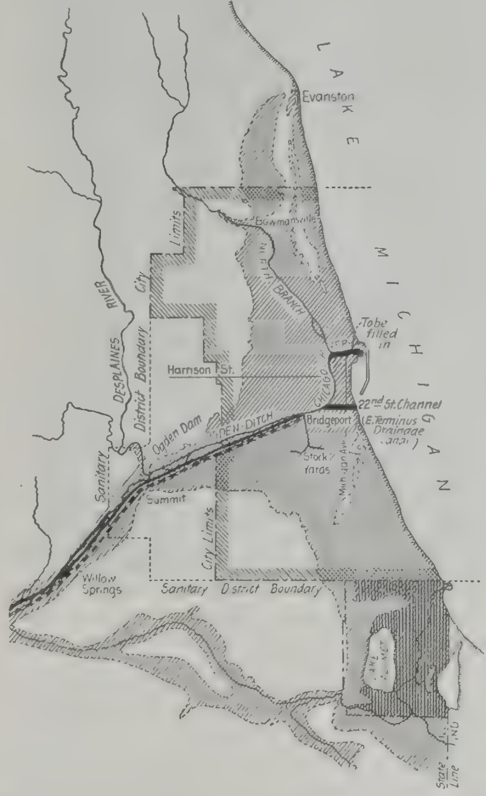
Taking the figures for 1894, the poorest year, and comparing them with similar figures of the traffic of New York harbor for the same year, we have the following results:

	Tonnage of vessels.	
	Entered.	Cleared.
Chicago	5,181,260	5,211,160
New York city	7,819,236	7,514,162

It would seem that a traffic by water only second in volume to that of the chief seaport of the country is well worth great effort and expense to preserve, especially since this traffic is one in which large sections of the country are deeply interested, and it is growing in amount each year despite the notoriously insufficient harbor accommodations.

The first question being thus disposed of, attention may be turned to the methods of accomplishing the necessary improvement. A study of the accompanying map will show that three methods are possible. (1) The construction of an outside or lake front harbor; (2) the construction of a harbor along the Calumet River at South Chicago; and (3) the improvement and development of the Chicago River in connection with the Drainage Canal. The lake front harbor has been placed first, not because of its importance, but because it is the least available solution and the soonest dismissed.

The practicability of a lake front harbor is doubtful for several reasons: (1) The length of lake front available is too small. It has been estimated by a competent authority that the space available for piers inside the present breakwater will give about 7½ miles of dock line or less than 20 per cent of the dock line at present used. If the breakwater were extended from Lincoln Park to Jackson Park, there would be about seven miles of shore line available if unobstructed. But the approach to at least 75 per cent. of this shore line is obstructed by the right of way of the Illinois Central R. R., and its possible riparian rights, and by the Lake Front Park, now under construction. (2) A lake front harbor would necessitate the transfer thereto of the entire business of the port with railway terminals and all the incidents of commerce, or else the cost of doing business would be multiplied by drayage and lighterage from the coal and lumber yards, grain elevators, packing houses, etc., now located from one to three miles inland. Briefly, then, a lake front harbor, if available in every other way, would either revolutionize the whole business and industrial arrangement of the city by its wholesale transfers or else involve a tremendous system of drayage and lighterage with all the increased expenses attendant upon such a system. The engineering questions of a lake front harbor construction need not be considered, for the reason that the business and industrial considerations seem to us to determine effectually the impracticability of such a harbor, except as a matter of last resort.



Map of Chicago Showing Site of Proposed Harbor Improvements.

(The area shaded represents surface below a plane 20 ft. above Chicago datum--low water in Lake Michigan. The area cross-hatched about the mouth of the Calumet River shows the area more than 5 ft. below Chicago datum.)

Before considering in detail the comparative advantages and disadvantages of the two other harbor possibilities, a few general considerations are advisable. On general principles it is certainly advisable to develop the facilities for commerce where the bulk of commerce already exists rather than to take the opposite course, and thus necessitate the destruction of great vested interests already existing, unless there is a paramount reason for the change. As shown by the tabular statement above, the business of South Chicago or Calumet harbor for 1895, estimated in tonnage of vessels entered and cleared, is about one-fourth that of Chicago harbor proper. On the single basis of best accommodating the greatest bulk of existing commerce, then, the improvement of the Chicago River would seem to be demanded rather than the improvement of the Calumet. Are there sufficient superior advantages at Calumet to counterbalance the disadvantages of changing commerce?

To enable a clear understanding of the possibilities of the Calumet River as a harbor, the accompanying map has been so drawn as to show by shading the area south of the mouth of that stream of which the major portion is below the level of 5 ft. above Chicago datum (low water in Lake Michigan). Altogether there are about 30 square miles of this area, of which there are normally under water about 14 miles (0.5 square miles) of river from 7 ft. to 10 ft. deep, with low, sedge-lined banks, and about six square miles comprised in Lakes Calumet, Hyde and Wolf, with a maximum depth of about 3 ft. below Chicago datum and with flat, marshy shores. At times of high water in Lake Michigan about 20 miles of this area are below lake level. Now it is this land that must be the site of a city, for transferring the harbor and commerce to the Calumet means the transfer of the industrial population supplying that commerce, and it behooves us to consider its adaptability to this end.

It is evident that the topography of the land necessitates the raising of a large portion of its area adjacent to the water courses in order to fit it for building, and also that the dredging of a large area to provide the necessary deep water for vessels is necessary. The cost and difficulty of building on such "made ground" overlying a bed of muck and sand are well known. As the level is such that the water courses will be motionless unless flow is induced artificially, it is evident also that the difficulties of drainage, sewerage and general sanitation are very great. In short, commerce and population will bring here their thousand and one problems and difficulties, as great and probably greater than have attended the growth of Chicago itself.

If we put aside these broad commercial considerations and confine ourselves purely to the question of providing a certain area of channel of a certain depth, width and freedom from curves, it can be done more easily at Calumet than anywhere else, perhaps, in the Chicago District. The topography is reasonably favorable to great freedom in such work, and so also are the small number of vested interests to be disturbed. Many things which incommode such constructions in a populous district do not exist here, and in these respects the Calumet has superior advantages over the Chicago River. It is upon these favorable circumstances alone that the claim or superiority for the Calumet River harbor site is based. Doubtless there are advantages to be utilized, but in another way, of which mention will be made further on.

Leaving the Calumet for the present, let us turn to the harbor possibilities on the Chicago River. In the first place we find 75 per cent of the lake business of the "Chicago District" already established along its banks. Quoting from a report of the government engineer in charge: "Along this stream are great lumber and coal yards, grain elevators, meat packing establishments and generally all the means and appliances and paraphernalia of the great commerce by lake centering at Chicago, as well as the facilities for transfer from rail to water transportation." The commerce and all its adjuncts, be it noted, is here; and it only remains to improve the river adequate to its needs. It is not necessary to build a harbor and commerce both, as at Calumet, for commerce surely implies buildings and railway terminals and population, in short a city, and these do not exist in the Calumet marshes. To improve the waterway adequate to the needs of commerce, is then the problem on the Chicago River.

Approximately the present length of the Chicago River and adjacent slips is 21 miles, and the number of lineal miles actually supplied with docks is about 40. These docks, on account of the peculiar Y-shape of the river course, are well distributed for the needs of commerce, being right in the heart of the business portion of the city. The river, however, is crooked and narrow, is crossed by numerous bridges, and its depth over the street tunnels under it is only from 15 ft. to 19 ft. To fit it for the demands of commerce it must be widened, straightened and especially increased in depth. With buildings and docks and railway terminals close to and along the whole length of its banks and with tunnels underneath its bed, such improvement is a large and difficult problem, but difficult more on account of the financial problems than on account of the purely engineering problems. In its most serious phases it is purely a business proposition, and if the proper interests conjoin, it can easily be solved as a business proposition.

Before urging this point further it is desirable to turn to another feature of the Chicago harbor question. Already the city has partly completed in the great Drainage Canal, what is practically an extension of the Chicago River, a distance of 28 miles westward. This channel has a depth of water of 25 ft. and a minimum width of 160 ft. (about one-half its length, and that on the portion adjacent to Chicago is 202 ft. wide). The law authorizing the channel demands that the volume of flow shall be at least 300,000 cu. ft. per minute, and an additional 20,000 cu. ft. per minute for every 100,000 increase in population over 1,500,000. The channel as built will pass 600,000 cu. ft. of water per minute. To provide the minimum flow, the Chicago River may be enlarged at an estimated cost of about $750,000, and to provide the maximum flow it must be doubled in size or else an independent supply channel must be constructed. This supply of water is a practical necessity which confronts the city of Chicago unless the Drainage Canal, costing some $30,000,000, is to be useless. This necessity also at once suggests that the construction of an adequate harbor for Chicago should go hand in hand with it. The same enlargement of the Chicago River or construction of a supply channel that completes the Drainage Canal constructs a harbor for Chicago, or at least can be made to do so without the slightest injury to the canal as a sanitary work, and at no inordinate increase of expenditure.

It may be argued, of course, that the supply of water for the Drainage Canal can be furnished through the Calumet River by extending that stream west to connect with the canal about midway of its length. So, indeed, it can, but with no advantage to Chicago or to the canal, but only an advantage to the Calumet River and the few large property-owners who control the land along its banks. The population tributary to the Chicago River, which has paid the great bulk of the cost of the canal, can hardly be expected to forego the possible commercial benefits of their expenditure for the sole benefit of the population which has paid but a very small part of this cost, and this is to what the development of the Calumet River as a feeder amounts. Above all this, however, is the policy of the Sanitary District of Chicago, which controls the location of the water supply to the Drainage Canal, and this policy as far as it is defined is to take the supply from Lake Michigan through the city of Chicago.

Assuming that the harbor improvement and drainage work is to be done conjointly, the engineers of the Drainage Canal maintain, we believe, that only two alternatives are presented, either (1) all the water for the Drainage Canal must be taken through the Chicago River, or (2) all must be taken through an independent supply channel. The reason for this is because if both routes are used (the river and the new channel each supplying part of the water) the floods coming down the North Branch of the river instead of passing down the South Branch to the canal will in part at least go east into the lake through the main river. Now, to make the river capable of supplying all the water required by the Drainage Canal its cross section will have to be about doubled, which, with all the property interests along its banks means a tremendous expense. On the other hand, if a supply channel be excavated from the lake to the South Branch, the main river mouth must be closed. The preferable plan can be determined only by the determination and detailed comparison of the financial and engineering conditions governing the two routes, and these data are not yet available in detail, although they have been determined for the most part by the engineers of the Drainage Canal.

In a general way the engineers of the Drainage Canal announce that a channel 250 ft. wide and 22 ft. deep from the lake along 22d St. to the South Branch, and thence to the Drainage Canal, will cost about $10,000,000 with all bridges and approaches complete. By filling the river from its mouth to the fork, a strip of land 200 ft. wide and one mile long is regained right in the heart of the city. The value of this, about 26½ acres of land, has been estimated to be from $15,000,000 to $18,000,000, based on real estate values in the business section, which, it is claimed, will probably more than counterbalance the destruction of dock property necessitated by the filling. Of course the main bulk of the dock property, which is along the two branches of the river is not affected at all.

By the arrangement outlined, the city would secure a 22-ft. channel from the lake to Lockport, Ill., nearly 30 miles, both banks of which are available for docks and slips, and also the present river channel undisturbed north of 22d St. except for the closing of the present main outlet about one mile. This river, when dredged, will give a navigable depth of 15 ft. without disturbing tunnels or other structures crossing it. This supplies a harbor equal at least to anything possible at South Chicago, and right in the heart of the commercial development which demands it.

The only doubtful feature in the above plan appears to us to be the proposition to fill in the present main channel of the river. The advantage of eliminating all the bridges and tunnels which now separate the North Side from the main business district of the city, is, of course, an attractive one; but, on the other hand, the opposition to so radical a change is sure to be extremely powerful. As the river is a navigable waterway, Congressional sanction will doubtless be necessary for its abandonment as proposed; and the interests which will oppose the change, including the owners of property, docks, etc., along this two miles of water-front, can be relied on to oppose the proposition at every step of its progress.

It appears to us that the reason given above by the Drainage Canal engineers for filling the present main channel of the river are hardly weighty enough to warrant so enormous an undertaking. If there is danger that with two independent outlets to the Chicago River, one of them would discharge into the lake in times of flood, the proper course to pursue, it would seem, would be to build a lock in the new 22d St. channel, and let the gates be closed whenever floods would cause a flow in this channel toward the lake. As there are very few days in the year when this would occur, the lock gates would be open practically all the time, and would be no obstruction to navigation of any importance. Again, with two channels existing instead of one, obstructions due to a wreck in the channel, a drawbridge out of order or other temporary block to one of the channels would be of comparatively little importance. The current in the channels, also, would be of less velocity if both channels were open than if one had to carry the entire flow. It may be claimed that the engineers have designed the new 22d St. channel of such capacity as to carry the maximum flow of the canal without a velocity of current so great as to interfere with navigation; but if this is the case, would it not be better to save part of the cost of the 22d St. channel by reducing its dimensions?

The value of the land which would be acquired by filling the present Chicago River may be used as an argument for the work; but we should like to see more of the details on which this estimate is based. Would not the depreciation and property damage consequent upon the abandonment and filling up of this waterway amount to more than the value of the area thus acquired? Would not the carrying out of any such work, moreover, be made still more expensive by the delays which interested property-owners would doubtless bring about by prolonged litigation?

But the question whether the present main river should be abandoned or not is only a detail. The chief question under consideration is whether the Chicago or the Calumet shall be the seat of Chicago's shipping trade; and the outline above given seems to point clearly to the former as the common sense solution of the problem. The cost of the work will be great, of course, but that it will be so very much greater than the cost of an equally adequate harbor along the Calumet River is not so very evident. Even if it is greater, expense alone is not germane. The question is rather where the expenditure will make the largest returns in serving commerce. Even if we admit that superior facilities for harbor development exist at Calumet, the people will not ship commodities there unless it becomes the marketing point. If it does become the marketing point, the railways will go there and the population as well, and the burden of commerce will be shifted to a new point and divided. The problem is to be solved on the ground where it exists, just as the track elevation and drainage problems of Chicago have been solved. Amputation is sometimes necessary, but we do it only to save life and only after other resorts have failed. Rather, we try to cure and heal the injured member, knowing that in a partly crippled state even it is better than no member at all. And we never attempt to amputate the body to stick it onto someone else's sound limbs, and this is practically what trying to transfer Chicago's lake business from the at present crippled Chicago River to the youthful Calumet amounts to.

The Calumet River is doubtless one of the several natural advantages which Chicago possesses for developing a certain class of commerce, namely, commerce by water, and it should be improved for this reason. But the Chicago River is a similar and older and at present more important advantage for the same purpose. By accretion—the manner in which all commerce grows—it has developed a water traffic of great and growing dimensions, and now that improvement is necessary to increase and maintain this commerce, it should not be withheld. The opportunity for this improvement and the manner in which it may be brought about have already been suggested, but the facts necessary for a detailed discussion are not yet available, nor indeed are they necessary for the present purpose, which is to point out the broad salient factors entering into the problem of improving Chicago harbor.

To summarize briefly:

(1) The impediments to navigation at Chicago must be removed, i. e., the harbor facilities must be improved and extended, if commerce is not to be burdened in competition with other lake ports.

(2) A lake front harbor cannot be seriously contemplated as practicable with its present encumbrances, and the necessity of transferring business and facilities for business or establishing a vast system of drayage and lighterage.

(3) Facilities for commerce should be provided where commerce exists, for if commerce can be shifted at all, it cannot be shifted without also transferring population and facilities for business, i. e., destroying vested interests. Adjacent possible harbors as at Calumet are useful for developing subsidiary business centers and should be improved as such interests demand, but not to the neglect of the harbor already handling the bulk of the commerce nor with the idea of replacing the main harbor, unless the latter is incapable of improvement.

(4) Chicago harbor is capable of improvement by prosecuting work conjointly with the Drainage Canal work, and with comparatively little disturbance of vested interests.

LETTERS TO THE EDITOR.

Diagram of Frog and Switch Values.

Sir: Refering to your issue of July 2, p. 15, "Diagram of Frog and Switch Values," it might have been well to have added that the formula and diagram refer to track of 4 ft. 8½ ins. gage, and to a switch throw of 5 ins. By some this would be understood, but possibly not by all.

Yours very truly,
H. S. Jones.

Marion, Ohio, July 6, 1896.

Civil Service Examination for Construction Inspector.

Sir: On August 5, 1896, the New York City Civil Service Board will hold an examination for the position of Inspector of Construction, at 10 o'clock a. m. Candidates must have a knowledge of massive masonry in difficult foundations, pile work, sewer work, street work and pipe laying. Any citizen of the United States over 18 years of age is eligible. Applications may be obtained from the undersigned. The examination will be in writing, arithmetic, experience and technical knowledge.

Yours respectfully,
S. William Briscoe, Secy.

New Criminal Court Bldg., New York city, July 14, 1896.

English Sewer Flushing Practice.

Sir: Adverting to your issue of May 21, may we supplement for the interest of your readers, your article on English sewer flushing practice in that number, by giving you the point proved by the Douglas inquiry, viz., that of the syphons used by the 79 corporate bodies asked, 64% are of our own manufacture, as against 36% of all other makers combined. To us, as makers of the original deep trap syphon, such a proof of the superiority of our apparatus is very encouraging.

We are, yours faithfully,
Adams & Co.

York, England, June 23, 1896.

Car Storage Tracks in Railway Yards.

Sir: In referring to that part of Mr. Appleton's letter in your issue of July 9, commenting on the article, in the June 18 issue, on yards and terminals, which states that it is preferable for storage tracks for empty cars to have both ends open: In my own experience I have found that empty-car storage tracks are more likely to give trouble if open at both ends than if closed at one end. In the former case the cars are constantly being crowded toward the lead at the far end, where they often foul in trying to pass a common point. As to empty-car storage tracks being made the length of an ordinary switch engine draft—this would be all right if the cars were always handled in lots of that length.

Respectfully,
W. L. Derr.

Port Jervis, N. Y., July 13, 1896.

Stability of Steep Earthwork Slopes in the Tropics.

Sir: Noting what Mr. Silvanus Miller, M. Am. Soc. C. E., says in your issue of June 25, with regard to steep slopes standing better in some cases in the tropics than flatter slopes, and your comment on the same, I would add that it is not necessary to go nearer the tropics than South Carolina to find instances in which this is the case. On the South Carolina & Georgia R. R., near Aiken, S. C., there are cuts through a red clay in which it has been found that the banks having a slope of less than ½ to 1 stand much better than those nearer the more common slope of 1½ to 1.

The reason in this case seems to be that the surface becomes baked so hard by the sun that on the steep slopes the rain seldom breaks through this crust, while it is much more likely to do so on the flatter slopes.

Respectfully,
C. S. Phelps, Civil Engineer.

Charleston, S. C., June 29, 1896.

Very Low Prices for Reservoir Construction.

Sir: At a bidding this week in a town on the Ohio River, the present tendency toward low prices was well illustrated. Walls 17 ins. thick, of stone laid in cement with the face well plastered to insure a perfect joint, were offered for $2.00, and some stone are expected to be in the excavation. This work is to be done on a very steep hill with no roads leading to it and no water nearer than 1,000 ft. Sand is about the same distance away. The hill has an elevation of 200 ft. above the town. For concrete in the bottom 6 ins. thick with a top coat of Portland cement, $2.40 per cu. yd. was bid.

The settling reservoir, 15 ft. deep, will have 17-in. stone walls and a 17-in. partition wall through the center. It is partly in excavation and partly fill and was let at 12 cts. per cu. yd. and $2.50 per cu. yd. of masonry, the latter including plastering the face of the wall. The concrete bottom in this is to be 6 ins. deep with a Portland cement facing and was let at $2.75 per cu. yd.

Other prices were as follows: Pipe laying, including cost of lead, 10 cts. per ft. for pipe 6 to 8 ins. laid 3 ft. 6 ins. deep. Pipe, $18.65 cts. per ton for 22,500 lin. ft., of which 12,000 is 4-in. Specials, 2⅛ cts. per lb. Hydrants, double-nozzle, 4-in. inlets, $15. Intake well for air-lift pump, 25 ft. deep, 7 ft. diameter, 13-in. brick walls, $300. Yours truly,

A Bidder Who Was Too High.

July 9, 1896.

An Incident of the St. Louis Tornado.

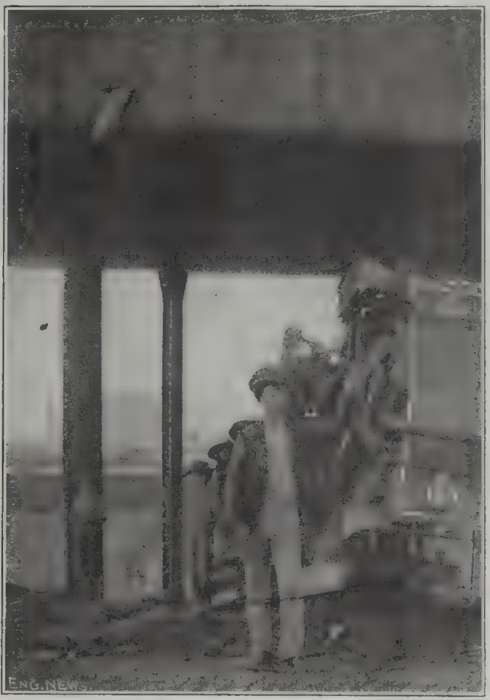
Sir: The enclosed photograph, which shows somewhat faintly a piece of wood driven through the web of a plate girder, is of interest as indicating the high velocity of the wind which prevailed during the St. Louis tornado.

The timber specimen itself, though quite inaccessible, was gathered in early by some enterprising relic hunter, before the writer had an opportunity to examine it closely. As seen from the track above, on the day after the storm, it appeared to be the end of a 2 × 6 in. pine plank that had been driven about 4 ins. through the girder web and then been broken off and somewhat shattered.

The girder shown is on the south side of the through girder span at the east end of the approach to the Eads bridge, in East St. Louis. It had been in use 20 years and is in good condition. The web plate is of 5-16-in. iron and 6 ft. deep.

The hole in the web of the girder is below the level of the track and 15 ins. above the bottom of the girder.

An irregular shaped piece of metal, 9 ins. long and 1¼ to 2 ins. wide has been punched entirely out of the 5-16-in. web plate. The upper and right hand edges of the hole are nearly straight and in the plane of the web sheet. At the bottom and at the left hand corner, the plate is bent inward, irregularly, the maximum distortion being 1¼ ins.



Pine Plank Driven Through a Plate Girder on the East Approach to the Eads Bridge in the St. Louis Tornado.

Yours truly,
Julius Baier.

Turner Building, St. Louis, Mo., June 27, 1896.

Comments on Track Standards.

Sir: It would have added much to the value of table "A" of "Standard Track of American Railways," published in your issue of June 25, if the weights per yard or the sectional area of the angle bars were given. We venture to say that a means of comparison between the sectional area of the joints and the weights of the rails, as used by the different roads mentioned in the table, would form a very interesting subject for study by railway engineers.

It would also have added interest, if, in connection with the bolts used, it was stated whether the figures given were the diameters of the bodies of the bolts, or the diameters of the tops of the threads, or, if the threads were spun on the bodies and raised above them or merely cut in the ordinary way.

It would be interesting to learn why one road—the Chesapeake & Ohio—used 9-16-in. spikes with a 100-lb. rail, and another—the Chicago, Rock Island & Pacific—used ⅝-in. spikes with a 60-lb. rail.

Very truly yours,
R. Hinchliffe & Co.

100 Washington St., Chicago, Ill., June 27, 1896.

(We believe that the weight of angle bars is generally proportioned to the weight of the rail. The bolt diameters we suppose to be in every case the diameter of the body, and spun or raised threads are used little if any on track-bolts. Our correspondent apparently thinks that the weight of spikes should be proportioned to the weight of the rail. We are not clear that this is the case. In a heavy rail with a great deal of lateral stiffness, the spike on adjacent ties help each other. The heavy rail, by reason of its broader base, is less likely to tip, and, as it indents the tie less, it has less up and down motion which tends to loosen the spikes.—Ed.)

Low Charges for Engineering Work.

Sir: Apropos of the efforts of your valuable journal to raise the profession to the high plane to which it is justly entitled and to educate the public up to a just appreciation of engineering services, we submit a clipping from the * * * which is illustrative of the reason why engineering is looked down upon, and why men of brains and experience are compelled to leave the profession or accept carpenters' wages.

(The clipping enclosed is as follows: Ed.)

The water-works committee reported a proposition from * * *, hydraulic engineer, to draw plans and specifications for the new system, including details or working plans with estimates of cost, etc., the work to be done by the engineer for $600. The proposition was accepted by the council by a unanimous vote. Work will commence at once on the plans and specifications, location of pipe line, etc. The completed plans will have everything in shape to advertise for the necessary material, labor, etc., to carry out the entire scheme, and it is expected the work will be well advanced before winter comes.

The work referred to means the procuring of a supply of water from * * *, a distance of about nine miles, and means final surveys and location of route, also surveys for intake, complete detail plans for probably two pumping stations, intake, steam and pumping plant, etc., reservoir, stand pipe, distribution system, estimates, specifications, etc.

This work will cost in the neighborhood of $225,000. (The city of * * * has power to issue bonds to the extent of $250,000). There will be no difficulty in estimating from this what would be a fair percentage for proper engineering service.

The gentlemen referred to in the clipping is City Engineer of * * * and possibly on this account can afford to do the work cheaper than the private engineer; but the fact remains that such men do more real injury to the profession in one year than all the technical journals can counteract in two; and the average town committeeman (not without reason) has come to the conclusion that he can purchase professional skill as he would potatoes and about as cheaply. Can you not give your readers the benefit of your opinion on this subject.

Correspondent.

June 17, 1896.

(We publish the above letter as received, merely substituting blanks for the names of persons and places. As evidence of the fact that the tendency to cheapen engineering service does not come entirely from the beginners in the profession and those who call themselves engineers on a very slim foundation of training and experience, we may remark that the engineer criticised is an Associate Member of the American Society of Civil Engineers. In reply to our correspondent's request for our opinion, we would say that according to our best judgment, in engineering as in other things, people are very apt to get about what they pay for. The city that thinks it is going to get $5,000 worth of engineering work for $600 will be pretty sure to find itself disappointed. No engineer, no matter what his ability or experience, can afford to give an enterprise the study, investigation and examination it should properly receive if his compensation is fixed at a sum barely a tenth of what the work is fairly worth.—Ed.)

An Experience with a Cheap Engineer.

Sir: There are a number of small towns throughout the country which aspire to possess water-works. They appoint commissioners who think a civil engineer ranks about, not quite, with a good mechanic, and if he wants over "twenty shillin" a day it is too much. So they begin to write letters to different engineers and see who will come cheapest and get up their plans and specifications. I am sorry to say there are some "cheap engineers" to be had; and the result is generally disastrous to an honest contractor who wishes to bid on the work and make a fair profit.

He tries to bid according to the specifications, but finds if he does so he will be too high; and if he bids low, according to the way he thinks the work will eventually be done, and he is not the chosen one of the "cheap engineer's" fancy, he will get most beautifully left if he is unfortunate enough to get the work. For an illustration, I would like to give a few extracts from a specification for works recently advertised to be let in your paper. I have a copy of the said specification and shall preserve it as a curiosity. I would send it to you to be printed, but I fear some other "cheap engineer" might see it and learn some new tricks.

I was employed by a contractor to help him make up his bid. We, with about a dozen other contractors, began to ask questions of the "engineer," as the specifications left so much to the imagination, and as for the plans—well, as one of the bidders remarked, "I never seen nothing like it in over 35 years' experience." I will simply remark that the plans, what there was of them, showed how the work was NOT to be built.

I quote from the specifications:

Plain cast-iron pipe shall be, hub and spigot, 12 ft. in length, exclusive of bell (which shall not be less than 3½ ins. in depth), smooth, sound and perfect, and be coated inside and out with coal pitch and oil varnish, and not vary more than 4 per cent from the weights herein specified.

That reads like an "old chestnut," as all pipe is supposed to be made that way, and generally is, regardless of engineers' specifications; but on searching carefully this interesting document we find that there are no weights specified.

On asking the "engineer," he answered: "The usual weights." Then the bidders rally around the commissioners, and they, under pressure, issue a "supplement" (which I enclose), specifying that the weights shall be "as per Radford, Va., Pipe Co. Standard."

Next, specifications call for a "reservoir 125 ft. × 50, and 10 ft. deep, partly in excavation and partly in embankment (by the way, the commissioners said the reservoir was not to be built that way, as any fool would know if it was made that way the concrete lining would crack, so it was going to be made all excavation, no matter if the plans and the 'engineer' did say the contrary). The bottom shall be covered with concrete 8-ins. thick, and the sides with concrete 18-ins. thick, and shall be made water tight. The concrete shall be composed of Portland cement, sand and broken stone to be approved by the engineer and mixed and placed in the work as he directs."

The contractors asked the "engineer" in what proportions this concrete was to be mixed, and he replies, "the usual proportions." On being pressed for his version of "the usual proportions," he said "equal parts, one each of cement, sand and broken stone; you know you can't get concrete too rich."

Some of the contractors left without making a bid, knowing it was of no use, as events proved. The "particular" contractor bid $5.50 per yard for this "rich" concrete, probably knowing if he got the job he would not have to make it quite so rich. These are only a few of the "incidents" in these plans of what was not intended to be built, and specifications that did not specify. I only mention these two as a specimen and to show what engineers and contractors have to contend with.

Respectfully yours,
"Victim."

New York, July 1, 1896.

(We may add to our correspondent's very interesting letter that vexatious as the case is for the contractors who encounter such "cheap engineering," the case is vastly worse for the towns or cities for whom such work is done. The taxpayers there are the sufferers, and in the end will have to pay for every dollar saved in the engineer's fees, many dollars in increased cost of work or work badly designed and improperly carried out. Beware the counsel of a cheap adviser, is a proverb that is true of engineering advice as of any other.—Ed.)

Testing Work at the Massachusetts Institute of Technology.

Sir: I have been very much pleased from time to time to receive in the "Technology Quarterly" the results of tests made in the engineering laboratories of the Massachusetts Institute of Technology, which are referred to in your editorial of July 2.

Assuming them be made with care, I have found them to contain very valuable information for use in my office; in fact, additional knowledge for the profession which I have been unable to find elsewhere.

I must thank the Institute for turning its attention to these practical problems which we need to have solved, and giving us the results as early as practicable; though I agree with you that some of the results should be explained more fully.

Respectfully yours,
Hiram Mills.

66 Broadway, Lowell, Mass., July 8, 1896.

◆

Sir: Your editorial notes in your issue of July 2, on the pamphlets entitled "Results of Tests in the Engineering Laboratory of the Massachusetts Institute of Technology," seems to call for a few words by way of reply. The objections made are, as I understand the editorial:

1. That there is no index.

2. That the tensile tests of steel and iron have not been classified, but are arranged in the order in which the tests were made.

3. And mainly, "the lack of any summary of results, or of any explanation whatever, as to what the tests are intended to show, and do show."

4. By way of emphasizing the above, you say, "Then why not say, boldly and plainly, just what information of practical value is contained in this labyrinth of tables? In the absence of some guide of this sort, we greatly fear that the busy practising engineer will never attempt a search through this bewildering mass of figures merely on the chance of digging out some valuable piece of knowledge."

It should be observed that these pamphlets are reprints from the "Technology Quarterly," and are published in order to furnish to engineers, as early as possible, the results of tests made in the engineering laboratories, particularly those made on full size pieces, and under practical conditions; so that they may have at hand, at as early a date as possible, the additional knowledge furnished by the individual tests, without waiting until such a complete series should be made as to warrant drawing extensive conclusions of a general nature. It, therefore, seemed unnecessary to provide each pamphlet with an index of its own, as the headings, with the classification of subjects now used, would, of themselves constitute some sort of an index. On the other hand, there certainly will be a classified index when a larger number of pamphlets have been issued. That a good classification is desirable is, of course, true, and efforts will always be made to improve the classification. The persons to whom the pamphlets are primarily intended to be useful, are, precisely, the "busy engineers," and they have not, as a rule, the time to map out the amount of knowledge on a certain subject, and to proceed to deduce theories or formulas; but their special interest is with the particular problem that they have in hand.

Thus, if the "busy engineer" proposes to use a certain timber column with a bolster, the results of a few tests on full size columns with bolsters, such as he will find in the summary given on page 231 of Vol. III., will give him information as to the real strength on which he can rely, such as he cannot obtain elsewhere, as far as I know.

Moreover, I have, a number of times, known "busy engineers" to consult these, or similar tests of full size pieces to decide upon what to do in some important work. I have also had a number of letters from prominent engineers, expressing the opinion that these results will be valuable for reference in their offices.

In giving the results of tests, accompanied by suitable summaries, but without attempting to theorize, or draw conclusions of a general nature, we are following the example of other engineering laboratories, such as that at Munich, that at Berlin, that at Zurich, and that at the Watertown Arsenal. I will add that the tests that have been made on full size pieces, furnish a good deal of opportunity, in connection with tests made at other laboratories, to do a good deal of theorizing, and to overthrow certain ideas that have been handed down by tradition; but such study and discussion is an entirely different thing from a simple record of observed facts, which these pamphlets are intended to be. Moreover, it will be observed that Vol. III. contains more details (accompanied by summaries) than Vols. I. and II., and that it is intended to follow the method pursued in Vol. III. As to the high and low values of moduli of elasticity of certain specimens of steel, quoted in the editorial, I will say that these are not the only high and low ones in the tables, and that such values will be found also in the reports of other laboratories, as that at Munich, and that at Watertown Arsenal; hence, if these results are in error (of which there is no evidence) the error is one prevalent among other laboratories. Moreover, the work of which the results are published in these pamphlets that is performed by students, is done under such close supervision, and so carefully checked by trained instructors that the results have the same degree of reliability as though the tests had been performed by the latter.

One typographical error should be corrected in Vol. I., page 139, line 24 of the table, viz., the modulus of elasticity printed 21,813,000 should be 27,813,000.

As to the case of the pulsometer, possibly it would have been better to have figured both kinds of duty; so as to include both the cases in which the pulsometer is ordinarily used, instead of giving only one.

Very respectfully,
Gaetano Lanza.

Engineering Laboratories, Massachusetts Institute of Technology, Boston, July 8, 1896.

(Perhaps we should have said in our editorial note referred to that the defects against which our criticisms were directed, are by no means peculiar to the publications of the Massachusetts Institute of Technology. On the contrary, they are exceedingly common in engineering literature. This publication of detailed logs of tests without explanation or comment is partly a relic of the times—not so long past—when records of engineering tests of every sort were a rarity and engineers carefully preserved in their notebooks all they found. What we contend is by no means that published tests should necessarily be accompanied by the pet theories or ideas of the one who makes the tests. Our position is merely that if knowledge is to be imparted, it is the duty of the one who gives it to spare no pains in smoothing the path of the learner. Print a mass of figures in a table without explanation, and one engineer may, after difficult toil, find the valuable truth which the figures conceal. Add a word as to what is to be sought in the same table, and ten will benefit by it who could not spare time to hunt it out unaided.—Ed.)

LEGAL DECISIONS OF INTEREST TO ENGINEERS.

Regulations of Water Company.

A water company cannot shut off water from a water taker for non-payment of an old, overdue, and disputed installment of water rates, after having accepted payment for a subsequent installment. The water taker may prevent such shutting off by an injunction in equity, and the court cannot, in such proceeding be required to investigate the merits of the unpaid and overdue and disputed installment. The water company must resort to a court at law if it would enforce such claim.—Wood v. City of Auburn (Supr. Ct., Maine), 32 Atl. Rep. 906.

Notice of Defective Streets.

It is not necessary in order to charge a city with negligence or carelessness for defective street crossings, that notice of the defect should be brought to it by actual complaint. If the city carelessly and negligently permits defects to exist in its street crossings, no matter how caused, for so long a time that notice is presumable, then it becomes liable if a person is injured thereby, without fault or negligence on the part of such person.—Junction City v. Blades (Ct. of App., Kan.), 41 Pac. Rep. 677.

Prior Establishment of Street Grades.

The acceptance of a city charter by a town does not impliedly work an adoption by such city of street grades established by the town, so that the city cannot change such grades, without complying with a statute, forbidding a city to change a grade of a street which has been legally established unless damages are first assessed and tendered to the abutting owner.—City of Huntington v. Griffith (Supr. Ct. Ind.), 41 N. E Rep. 589.

Measure of Damages for Land Taken for Sewer.

The fact that the proximity of a sewer has a detrimental effect on land, part of which was taken for the construction of the sewer, so far as the injury is due to proximity secured by the taking of such part, and would not have resulted but for such taking, should not in determining the owner's damages be excluded as harm merely anticipated from the future use of the sewer.—Lincoln v. Commonwealth (S. J. Ct., Mass.), 41 N. E. Rep. 489.

Reasonableness of Water Company Regulations.

A corporation which has a franchise for supplying water to a city, and the use of the streets, becomes affected with a public use and assumes a public duty, and has a right to establish reasonable rules regarding payment of rates and to decline to furnish water to any one who refuses to comply with such rules; but to make such rule valid it must, in itself, be lawful and just, and must not be discriminatory in its nature.—American Water-Works Co. v. State (Supr. Ct., Neb.), 64 N. W. Rep. 711.

Assessment for Sewer.

Under Act May 16, 1891, providing for the appointment of viewers to assess the cost of a sewer on the property benefited, the cost of a main sewer can be assessed only on abutting property, and not on that of non-abutters having no present sewer connections, but whose property may be drained by future branches to be made. Where an abutting owner was assessed under such act, with the cost of a 15-in. main sewer, where a 10-in. local sewer would have been sufficient, the excess in the cost between a 10-in. and 15-in. sewer must be borne by the municipality.—Park Ave. Sewer (Supr. Ct. of Pa.), 32 Atl. Rep. 574.

Finalty of Engineer's Estimates.

An action was brought upon a written contract to recover a balance claimed to be due for work done in constructing a section of the defendant's roadbed. By the provisions of the contract, payments were to be made, during the progress of the work, on monthly estimates furnished by the engineer, 15% being retained until the completion. Upon the completion of the work, and its acceptance by the engineer, he was to make a final estimate of its quantity, character and value, and the amount ascertained by him to be due was to be paid to the plaintiffs. The estimates thus made by the engineer were to be final and conclusive as to both parties, subject to the right of the president to revise and alter them. Whether the last estimate furnished was final and fixed the rights of the parties was the principal question at issue. It was contended that it was because it was furnished after the completion of the work and was not revised or altered by the president. In form it was not a final estimate, nor such an estimate as was contemplated by the agreement. It was similar in form to the preceding monthly estimates, and was made, as they had been, at the end of the month, to show the amount of work done since the last estimate. But, like the preceding estimate, it showed the total allowances and payments. By agreement of the parties, expressed or implied from their acts, the court says this estimate might have become a final one, but neither party could arbitrarily make it such. It was competent for the defendant to show that a final estimate had been made by the engineer, fixing the quantity, character, and value of the work, and the amount due therefor, and testimony tending to prove this should have been admitted. The defendant should have been allowed to prove, also, that the engineer, at the instance of the plaintiffs, in order to enable them to meet their payments, had increased the amounts of the monthly estimates beyond what was justly due, with the understanding that, in the final estimate, a reduction of the proper amount should be made. The fact that the engineer was in the employ of the defendant, the court further holds did not commit it to the consequences of his misconduct while acting as an arbiter for both parties, and an award which was the result of collusion with the plaintiff was not binding upon it. It was the right of the president, under the agreement, to revise and alter the estimates made. This right he did not exercise, and his approval or disapproval of an estimate submitted did not affect its character as a final award of the engineer.—Gonder v. Berlin Branch Ry. Co. (Supr. Ct. of Pa.), 33 Atl. Rep. 61.

Engineer's Lien on Work Performed.

A civil engineer who makes field notes, maps, charts, and drawings, while employed by a corporation in and about the construction of an irrigating canal, on books and papers furnished by the corporation, the court of appeals of Kansas holds, is entitled to a lien on such field notes, maps, charts, and drawings, and has a right to retain possession of the same until he is paid for making the same.—Amazon Irrigating Co. v. Briesen (41 Pac. Rep. 1116.

Rights in Use of Tracks.

Railway companies with franchises to use the same street may be required to use one track, and in the exercise of this power a company may acquire the right to use the tracks laid by another, but compensation for such use must be made. If the tracks thus subjected to the common use of two companies are unfitted by age, long use or other cause, to serve the purposes of these companies, an action may be maintained by one against the other to compel the repair or reconstruction of the tracks at the joint expense of the companies.—New Orleans & C. R. Co. v. Canal & C. R. Co. (Supr. Ct. of La.) 17 So. Rep. 834.

NEW FOUNDRY OF THE NILES TOOL WORKS, HAMILTON, O.

The Niles Tool Works moved from Cincinnati to Hamilton, O., in 1871, erecting at that time what was considered one of the most complete shop plants of the day. It consisted of a machine shop, 65 × 400 ft., one section 40 ft. wide being used for erecting heavy work, and being served by overhead traveling cranes, operated by hand, and a foundry building, 50 × 200 ft., placed at right angles to the machine shop. The minor buildings need not be mentioned. As the business of the company grew, additions were made from time to time. To the north of the original machine shop and parallel to it was first built an erecting shop, with an overhead traveling crane, and a wing for tools, the whole covering an area of 75 × 400 ft. A little later another erecting shop, 50 × 400 ft., also served by overhead traveling cranes, and a two-story building, 50 × 400 ft., were erected. The second floor of the two-story building was used for milling machines, gear cutters and small lathes.

From time to time, while the above work was going on, additions were made to the foundry to meet the new demands being made upon that department. These additions were made in the form of bays, varying in width from 30 ft. to 48 ft., and in length from 300 ft. to 400 ft., and extending at right angles from the main building. Altogether six of these bays were constructed, each with an overhead traveling crane. Finally, it became necessary to enlarge still further and reconstruct the foundry, and the plan was adopted of building over the original foundry and extending north, with a central building 60 ft wide by 437 ft. long, the span to be served by two 30-ton overhead electric traveling cranes, with four motors each. This construction retained the bays which had been added from time to time, extending east and west from the original foundry building, and the same idea was carried out on the extension of the center building, on each side of the increased length of which are built a series of bays, six in number, 32 ft. in width. The cupolas and core ovens will remain in their present positions, but almost everything else will be entirely new, the old building being torn down piecemeal as the new one encroaches upon and overlaps it. The illustrations given in the cuts represent an outline of the ground plan of the new building and some of its more important details. As shown, it consists of a main molding floor, 60 × 436 ft., served by three 30-ton electric traveling cranes, with two smaller floors parallel to and adjoining it, one on each side, respectively, 30 × 240 and 30 × 196 ft., each served by 5-ton cranes, and in addition a series of bays extending at right angles to the main floor and on each side of it, some used for molding floors, others for cupolas, core ovens, core making, etc. Besides this there is a room of trapezoidal shape 199 ft. in length on its longest side for the storage of supplies. The whole area under roof is nearly two acres.

The building is constructed chiefly of iron and glass, as shown in the illustrations. It was designed by Mr. F. Felkel, Civil Engineer and Architect, of Pittsburg, Pa. The framework is unusually massive, the supports being designed for the double purpose of carrying the roof and of resisting the strains caused by the weight and the motions of the traveling cranes, and the roof trusses are built with reference to the possibility of some corrosion caused by the foundry gases as well as for mere strength. Much attention has been paid to the lighting of the foundry. A ridge lantern, 8 ft. high, extends the whole length of the main roof, and there are also roof skylights on each side. Altogether there are 32 skylights varying from 12 × 16 ft. to 16 × 16 ft. in size. Smaller skylights are placed in the roofs of the bays. All steel used has an ultimate strength between 65,000 lbs. and 75,000 lbs. per sq. in.

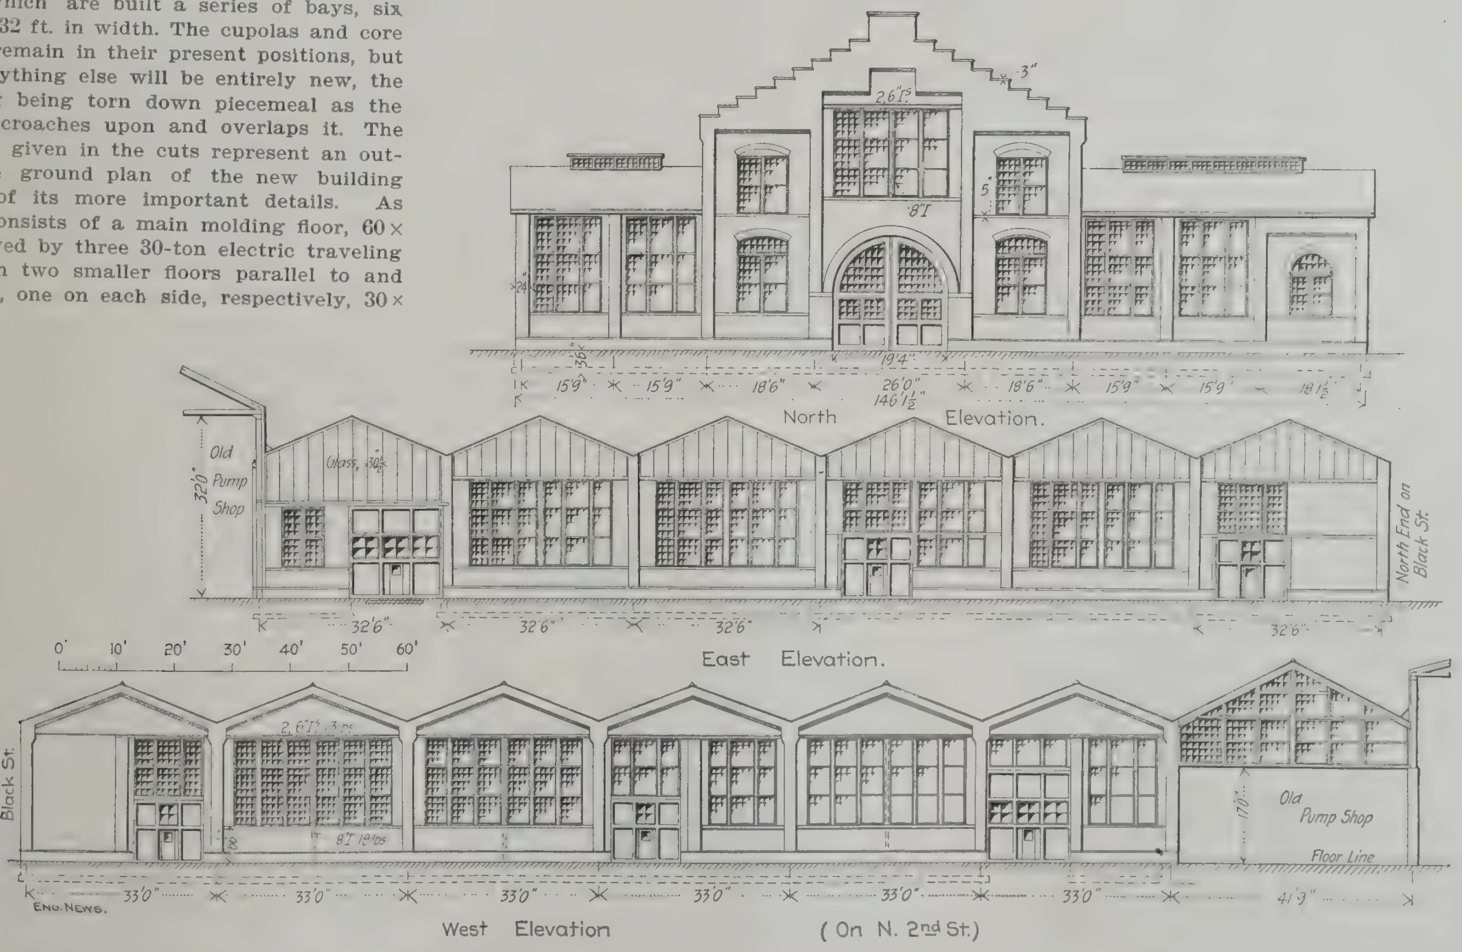
GENERAL PLAN OF FOUNDRY, NILES TOOL WORKS.

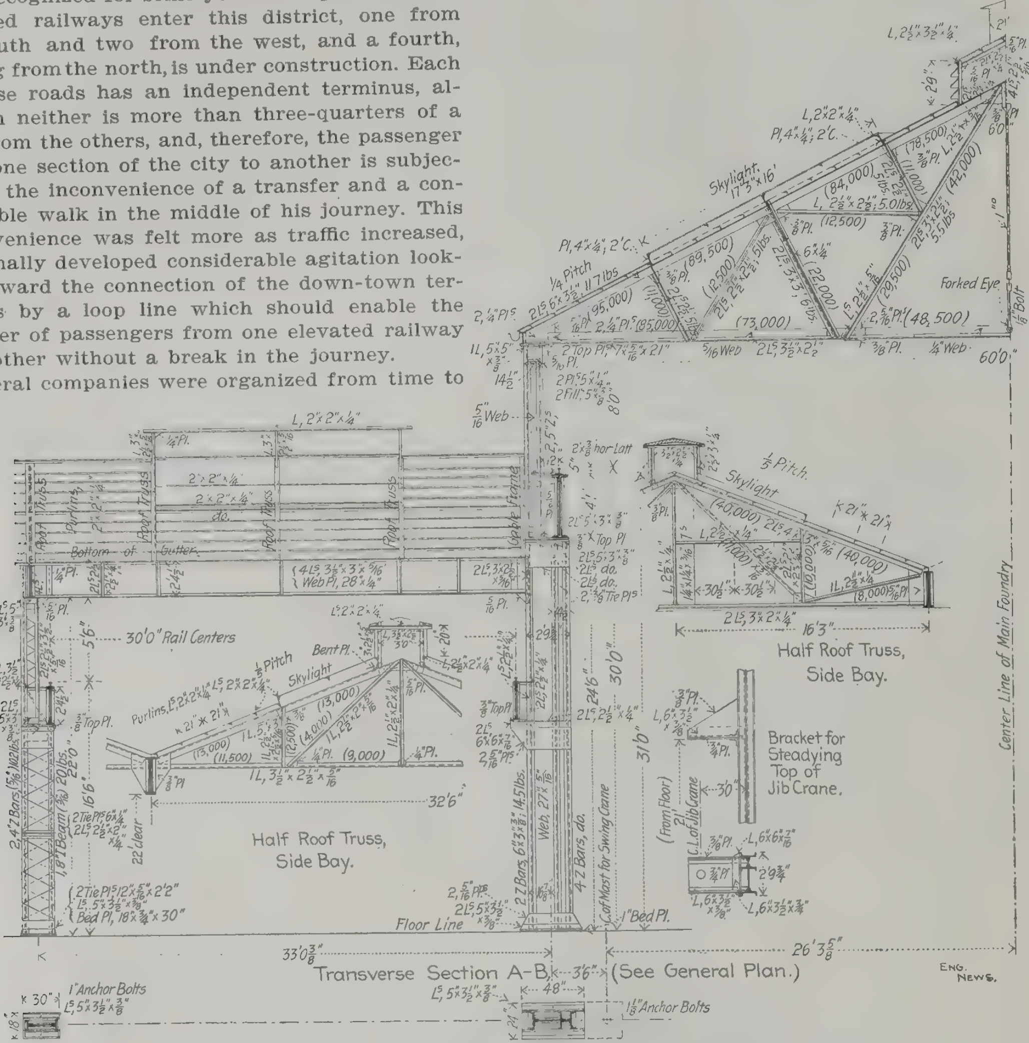
Besides first-class foundry machinery there are eight overhead traveling cranes having capacities of from 5 tons to 30 tons, and a large number of jib cranes. There are four large core ovens 12 ft. wide by 40 ft. long, and four small core ovens with rotary stands for shelf work. The main foundry cranes deliver all castings under the cranes of the machine shop without a second handling. For the drawings and information from which this article has been prepared we are indebted to the Niles Tool Works.



ELEVATIONS OF FOUNDRY, NILES TOOL WORKS.

A UNION TERMINAL FOR CHICAGO'S ELEVATED RAILWAYS.

The desirability of a union terminal line to connect the several elevated railway lines terminating in the central business district of Chicago has been recognized for some years. At present three elevated railways enter this district, one from the south and two from the west, and a fourth, coming from the north, is under construction. Each of these roads has an independent terminus, although neither is more than three-quarters of a mile from the others, and, therefore, the passenger from one section of the city to another is subjected to the inconvenience of a transfer and a considerable walk in the middle of his journey. This inconvenience was felt more as traffic increased, and finally developed considerable agitation looking toward the connection of the down-town terminals by a loop line which should enable the transfer of passengers from one elevated railway to another without a break in the journey.

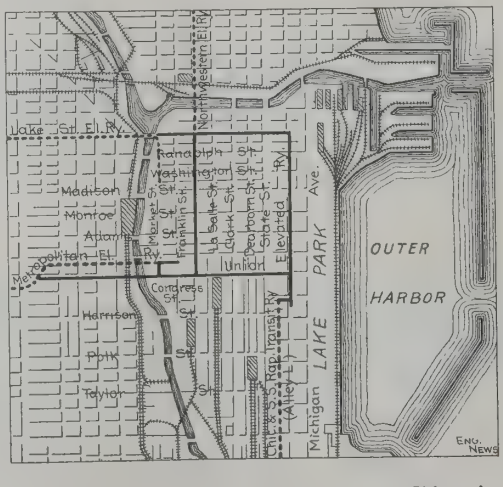


DETAILS OF ROOF CONSTRUCTION, NILES TOOL WORKS FOUNDRY.

Several companies were organized from time to time in the few years past to build this loop line, but none of them promised much until the Union Elevated R. R. Co. was formed by men interested in the various elevated lines to be served by the loop line. In October, 1895, an ordinance was granted to this company authorizing it to build an elevated railway along Wabash Ave., from Lake St. to Harrison St., and the work of construction was begun early last winter. Turning to the accompanying map it will be seen that this line connected the Lake St. Elevated Ry. at Lake St. with the Chicago & South Side Rapid Transit R. R. (Alley L) at Congress St. As soon as this ordinance had been secured the company began work to secure an ordinance for a second line along Van Buren St., from Wabash Ave. west to near Halstead St., and after considerable trouble with property-owners along the route it was finally obtained, by action of the City Council, on June 30, 1896. These two ordinances provide for the east and south sides of the loop, and efforts, it is expected, will now be made to get power to build a connecting link along Ffth Ave., to form the west side of the loop and complete the connection throughout.

In the accompanying maps the broken lines show the termini and routes of the four elevated railways to be served by the loop, and the solid lines show the route of the loop proper. All the elevated lines have two tracks, and the loop line will have two tracks on Fifth Ave. and Wabash Ave. and along Van Buren St., as far west as Market St. From Market St. west the Van Buren St. line will be single tracked. It should also be noted that a branch from the Van Buren St. line will run north on Market St. one-half block to a connection with the Metropolitan West Side Elevated R. R. This branch will be double tracked as will also undoubtedly be the west side of the loop along Fifth Ave.

According to a reported interview with one of the officials of the loop line, the manner in which the several elevated lines will use the loop is as follows: The Northwestern Elevated R. R. will connect with the loop at Fifth Ave. and Lake St., run east on Lake St., south on Wabash Ave., and north on Fifth Ave. to the starting point, using the outer of the two tracks. The Lake St. Elevated R. R. will use the same route as the Northwestern. The Metropolitan West Side Elevated R. R. comes in on the inner track at Van Buren St. and Fifth Ave., runs east along Van Buren St. and around the loop. The Chicago & South Side Rapid Transit R. R. will use the inner track north on Wabash Ave., and thence around the loop, but just how the connection will be made is not stated.



Map Showing Union Terminal Loop for Chicago's Elevated Rys.

The foregoing gives the general purpose and the method of using the union loop line. The ordinances which empower its construction regulate in a broad way the type of construction and motive power, and specify with some detail the compensation to be paid the city, and the extent to which the company shall maintain city property affected by its structure. Briefly, after the company has deducted $250,000 from its annual gross receipts for fixed charges, it shall pay to the city out of the remainder 5% per annum for the first five years, 10% for the second five years, 15% for the next ten years, 20% for the succeeding 15 years, and 25% for the remainder of the 50 years for which the franchise is granted. It should be noted that as first passed by the City Council, the ordinance provided for no compensation to the city, bribery of the Council being freely charged as being the means to this end. By threat of a veto and an array of the better class of aldermen, however, the Mayor was able to secure the agreement outlined, and on July 6 it was accepted by the Council and the railway company.

The ordinance requires that trains shall be operated by electricity or an equally clean and noiseless power, and it is generally known that electric power will be used. Two of the elevated roads which will use the loop now use electric power, a third is being constructed with this end in view, but the fourth, the Chicago & South Side Rapid Transit R. R. will have to change from steam to electricity. For this change the ordinance allows three years from the date of its passage.

In regard to the style of structure, the ordinance requires that it shall obstruct light and street traffic as little as possible, and to this end lattice girders, open floors and the wide spacing of columns are required. Street crossings are to be spanned by single spans when less than 70 ft. wide. The supporting columns are to be located at least 35 ft. apart longitudinally, and transversely just far enough apart to allow a double track street railway to pass between them. Minor details of construction are also specified, but as they require nothing unusual to ordinary first-class elevated railway construction they need not be mentioned.

The structure is required to be completed and in operation by Jan. 1, 1898, and, as already stated, construction is in progress; the Wabash Ave. line being well on toward completion and the Van Buren St. line just begun. According to the reports of the company's officials, the rapid prosecution of the work to completion depends only upon delays over which they will have no control. A five-cent fare will take the passenger to or from any point on the loop on any one of the lines connecting with it, but will not include transfer from one line to another.

A NEW HOISTING AND CONVEYING APPARATUS.

A new form of hoisting and conveying apparatus, known as the Temperley transporter, invented by Joseph Temperley, of London, England, has come into extensive use abroad, and the American patents on the system have recently been acquired by the Lidgerwood Manufacturing Co., of New York City.

The Temperley transporter employs an I-beam as a trackway, along which the load hoisted is carried by a carriage in either direction to the point desired. The beam is suspended either horizontally or at a moderate incline, and is provided along its bottom flange with a series of stops, at any of which, at the will of the operator, the carriage may be arrested and the load raised or lowered. These stops may be set as near one another as desired; 5 ft. is the usual standard. The beam or trackway may be of any desired length, and arranged, together with its support, in a variety of ways to suit the exigencies of the case.

A special feature of the Temperley transporter is the novel form of traveling carriage employed, the operation and mechanism of which will be readily understood from the accompanying cuts. It consists of two side frames, bolted together, with four wheels for traveling along the lower flange of the I-beam, a large sheave for the lifting rope mounted on the same pin as the suspender, a suspender for holding up the load when the traveler is moving, a pawl to prevent the suspender being lifted prematurely, a guard to keep the ball on the suspender hook when the traveler is moving, a double cam for locking the traveler to the beam when the load is being lifted or lowered, a single cam for locking the double cam, or securing the suspender when carrying the load, a sliding bolt passing through slots in the cams and frames for alternately locking the cams, a toggle to cant the tooth of the double cam into stops on the beam, and, finally, a check plate to prevent movement of the single cam when lifting or lowering.

Fig. 1 shows the traveler locked to the beam by the double cam, which is in gear with a stop. The double cam is prevented from moving by the sliding bolt, which is hard over to the right and within the straight part of the slot in this cam. The single cam is unlocked and the suspender hanging down and the rope free for lifting and lowering.

Fig. 2 shows the traveler moving down the beam with the load carried by the suspender. The suspender is held up by its bolt being in gear with the gab in the single cam. The single cam is prevented from moving by the sliding bolt, which is hard over to the left and within the straight part of the slot in this cam. The double cam is unlocked, and in such a position that the traveler is free to move up or down the beam. When one cam is locked, the other is always free. The double cam when free is actuated by contact with stops on the beam, the single cam is actuated by the movement of the suspender. The slots in the cam are so designed that the movement of the free cam causes the release of the locked cam, and the release of one effects the locking of the other. This reciprocal action of the cams automatically and simultaneously arrests the traveler and releases the load, or releases the carriage and secures the load. Figs. 3, 4 and 5 illustrate the most novel features of the carriage and explain the action of the double cam, whereby the carriage may be arrested by any stop along the beam. As will be seen the toggle in Fig. 3 is pointing upwards, but in passing the stop is turned to face down, and is cocked in that position, as illustrated in Fig. 4. Fig. 5 shows the cam in position for the carriage being lowered to a stop that it has passed. The toggle comes in contact with a notch of its own, which rocks the cam so that the tooth is projected up into the notch. This resists the further motion of the carriage, releases the load, and the carriage is locked. The beam is usually set at an angle so that the carriage travels in one direction by gravity. If, however, circumstances do not admit of the incline beam, then a counterweight rope is attached to the rear of the carriage and the carriage is pulled back by the falling counterweight.

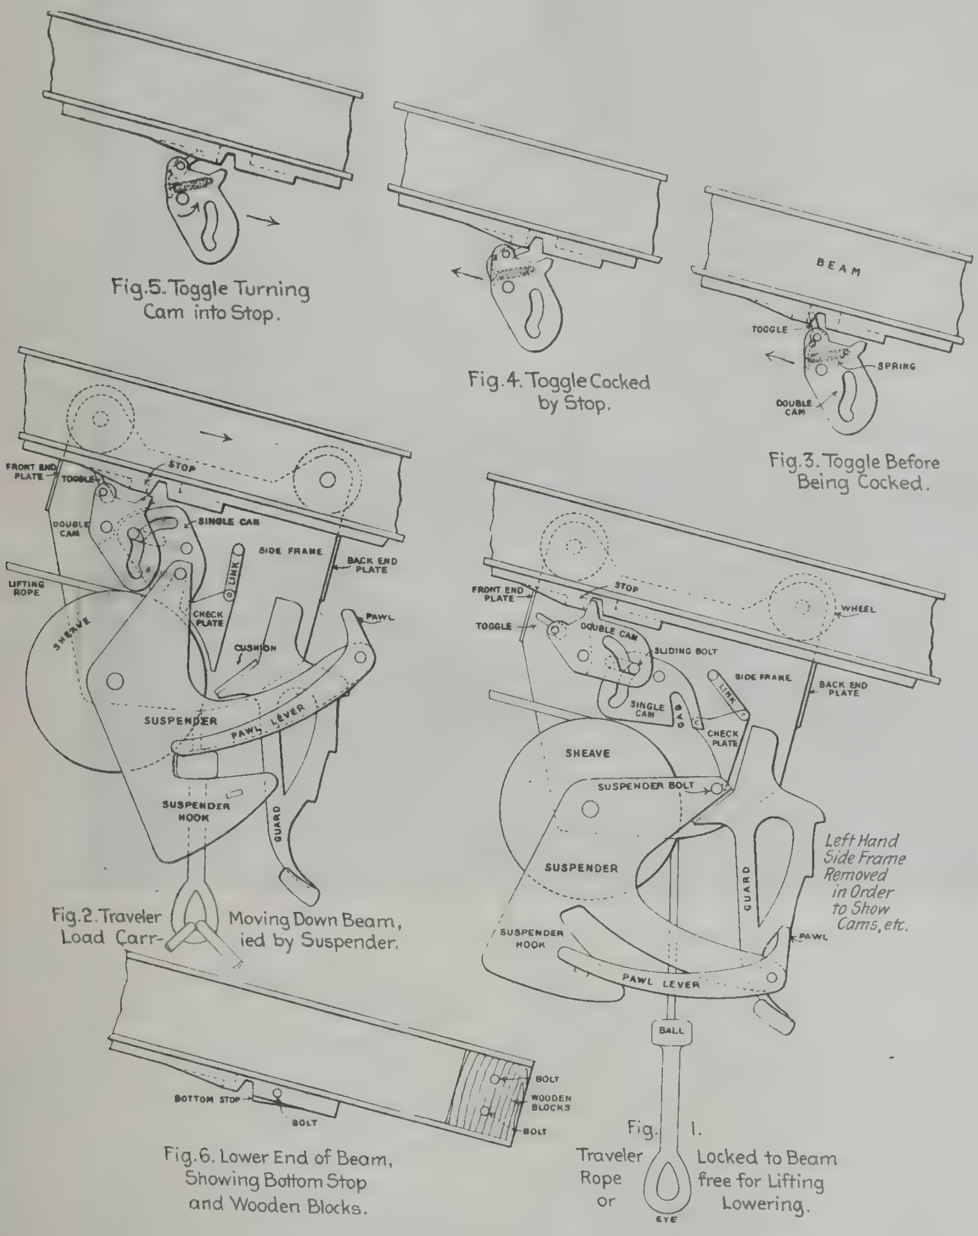

Fig.5. Toggle Turning Cam into Stop.

Fig.4. Toggle Cocked by Stop.

Fig.3. Toggle Before Being Cocked.

Fig.2. Traveler Moving Down Beam, Load Carried by Suspender.

Fig. 1. Traveler Locked to Beam Rope or Eye free for Lifting Lowering.

Fig.6. Lower End of Beam, Showing Bottom Stop and Wooden Blocks.

FIGS. 1 TO 6.—DETAILS OF CARRIAGE OF THE TEMPERLEY TRANSPORTER.

The great outreach of the transporter makes it particularly well suited for work along rivers where wharves are not provided. It has been put to a number of uses in England, notably for handling coal, both on wharves and vessels, also for stacking timber, discharging cargo, handling ore, coke, baled hay and cotton, and many other kinds of material which are conveniently handled in packages. It has also been used for coaling war ships at sea with great success, many transporters having been supplied to the British Admiralty, and also to the German, French, Austrian, Italian and Russian governments for that purpose. The illustration in Fig. 6 shows an installation recently completed for the carrying out of some public works at Clichy, on the river Seine, near Paris. A temporary wooden jetty has been constructed over the roadway and a timber structure put up to support the beam of the transporter. This beam is 53 ft. long.

The transporter is worked by an electric winch placed under a wooden shelter at the outer end of the jetty. A line of rails connects the jetty with the works, and the method of working is as follows: A set of six Decauville wagons are run on to the jetty under the transporter and these wagons are filled consecutively, the stops on the beam being so arranged as to plumb the center of each wagon. The material hoisted and conveyed consists of stone, gravel, cement, etc., and arrives in lighters which are moored immediately below the outer end of the transporter. The material is filled into tubs, which are hauled up by the transporter and dumped into the wagons, or the wagon bodies are removed from their wheels and lowered into the lighters to be filled. As soon as one set of wagons is filled, it is removed and another set shunted on to the jetty. This transporter has a lifting capacity of 3,000 lbs., and can discharge 50 tons per hour. The electric winch is operated by current from the generating plant at the works some distance away. The electrical energy required by the transporter when at full work is about 60 amperes at 200 volts. The installation at this place has proved very successful.

THE EARLY HISTORY OF STREET PAVING AND STREET CLEANING.

In his "History of Inventions and Discoveries," John Beckmann, Professor in the University of Gottingen, devotes a chapter to the paving of streets, and from this historical sketch the following more interesting points are taken:

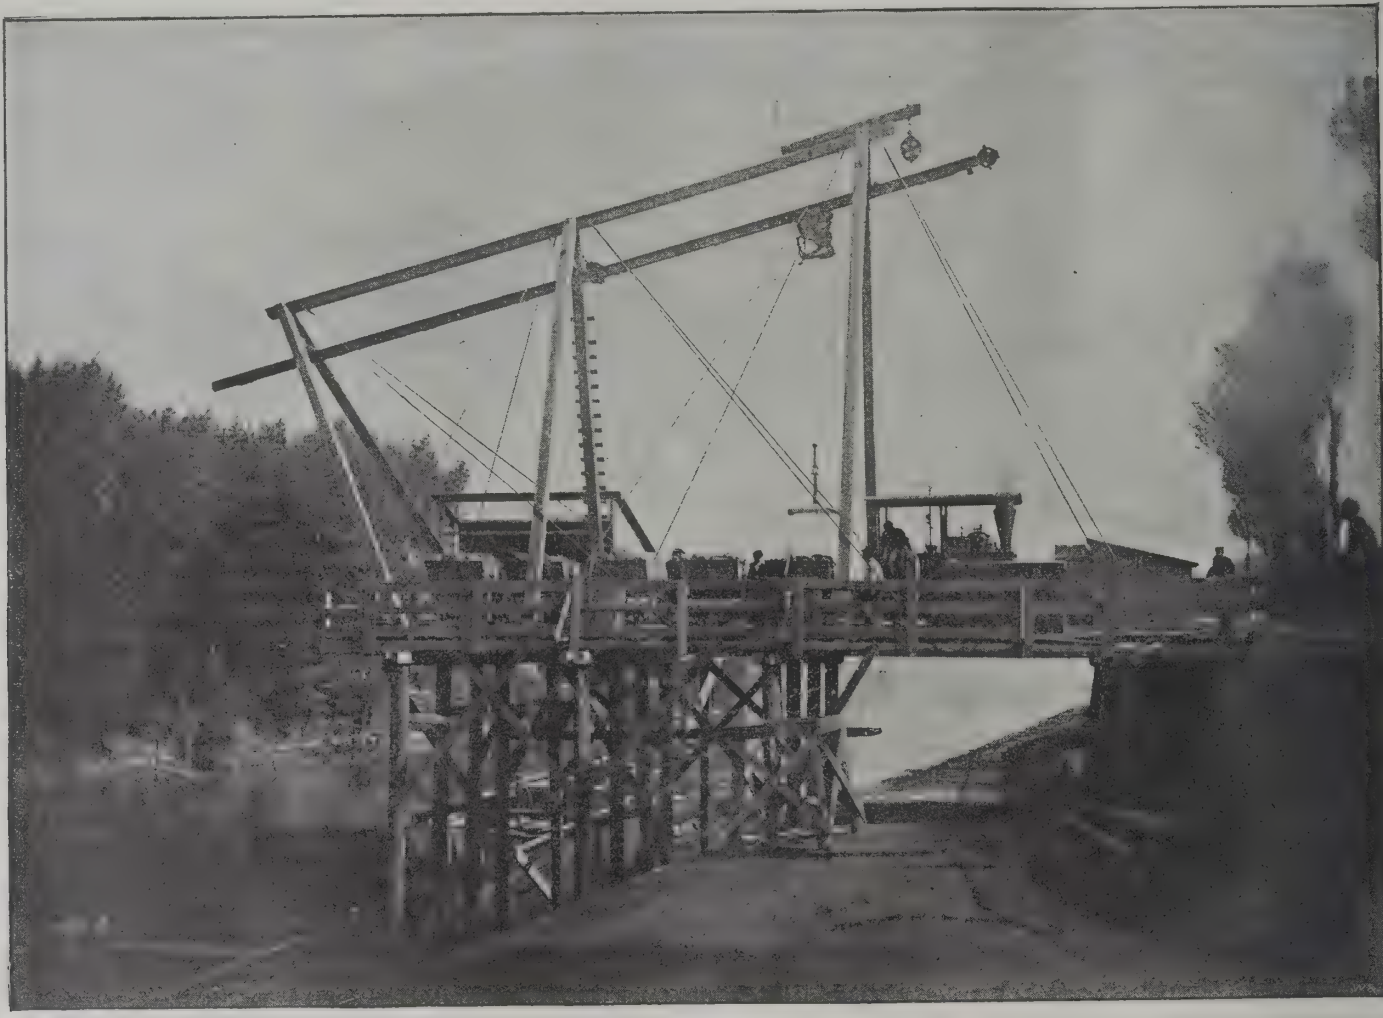
While Roman writers of early date often refer to paved highways and especially describe the famous Appian Way, of 565 B. C., there is comparatively little reference to the paving of streets in cities. The streets of Thebes were regularly cleaned under the inspection of the telsarchs, and it is to be assumed that they were paved; and the Talmud says that the streets of Jerusalem were swept every day, which undoubtedly implies a hard and solid pavement. There is no record of the first street pavement in Rome; but Livy mentions that certain streets were ordered to be paved in 169 B. C., and as early as 530 B. C. the Emperor Heliogabalus paved the streets around his palace with foreign marble. The streets of Pompeii and Herculaneum still show their paving blocks of lava, cut into deep ruts by the wheels of passing chariots.

Passing to later times, we find the streets of Cordova, in Spain, paved as early as A. D. 850, by order of the Caliph, Abdorrahman II. The first record of any street paving in Paris is dated in the year 1184, when the name of the city was changed from Lutetia, the dirty, to Paris. This innovation is said to have arisen from the fact that the King, Philip II., was annoyed by the offensive odors produced by the agitation of the mud in front of his palace by passing vehicles. He resolved to remedy the intolerable nuisance by ordering the streets paved, and succeeded in having this done, in part, at least, notwithstanding the heavy cost, which had deterred his predecessors.

In 1090 the streets of London were soft earth only; but when the first pavement was introduced is not known. Holborn was paved for the first time, by royal command, in 1417; Henry VIII. ordered other streets paved, and the great market square of Smithfield was first paved in 1614. Augsburg, in Germany, seems to have been the first city in that country to introduce footways and street pavement, in 1415, but the extension of the improvement to other towns was slow, and the streets of Berlin were not all paved even in 1679.

Street cleaning was only rendered possible by first providing some manner of hard surface to work upon. Rome had its "tribuni verum intentium" at an early date, officials who were charged with the care and cleaning of the streets, markets, temples, baths and other public places. Ordinances were framed, and more or less severely enforced, forbidding the throwing of any manner of filth into the river or into the streets of Rome. For some centuries after Paris was paved every citizen was compelled to repair the street before his house and to clean it at his own expense, in accordance with an edict of Philip the Bold, issued in 1285. This law was practically unobserved, however, and in the 14th century the streets of Paris are described as in a horrible condition. Later laws made street cleaning compulsory, for nobles as well as for the common citizen, and in 1501 a company was formed for cleaning streets by contract with individuals. Street cleaning at public expense, in Paris, was inaugurated in 1609, and the sum of 70,000 livres was appropriated for this purpose from the public fund. In 1704 the city collected 300,000 livres for cleaning streets and maintaining lamps.

A pig figures prominently in the first Parisian ordinances forbidding the deliberate dirtying of the streets. The young King Philip, son of Louis the Fat, was killed, in 1131, as the result of a fall from his horse brought about by a pig in the streets. As a consequence of this accident an order was issued forbidding swine running loose on the streets of the city; but this order was bitterly opposed by the monks of the Abbey of St. Anthony, who resented this affront to the charges of their patron saint, and demanded liberty for the swine to go where they pleased. After some time spent in controversy, the pigs belonging to this abbey were granted a special dispensation and permitted to wallow at will, provided that they had bells attached to their necks.



TEMPERLEY TRANSPORTER AT CLICHY ON THE RIVER SEINE.

Up to the 14th century, in Paris, and as late as 1750 in Edinburgh, citizens were permitted to throw from their windows any manner of slops into the streets before the house, provided that they called out three times before doing so. This privilege, so inconvenient to the passer-by, was strictly forbidden in Paris in 1395, and from this time may be dated the first introduction into that city of sanitary conveniences. It is interesting to note that when Columbus sailed for the Indies, the palace of King Ferdinand of Spain was destitute of any conveniences of this nature. The Parisian Code of Laws of 1513 expressly orders that every house should have a privy, and severe penalties were imposed for non-compliance with this order; but even as late as 1700 the police were compelled to use the utmost vigilance to prevent infraction of the law and to keep those in use in a fairly sanitary condition.

In Germany the cleaning of streets was at first considered as a most dishonorable employment, which in some places was assigned to the Jews and to the servants of the public executioner. Up to the beginning of the 17th century the streets of Berlin were never swept, and pigs ran at large throughout the city. In 1624 the Elector desired the Council to have the streets cleaned; but the Council replied that it was impossible, as the citizens were busy on their farms. The dirt in the public market place accumulated to such an extent that in 1671 a law was passed compelling every countryman to take out of the city one load of dirt every time he came to market. Pig-sties in the streets were common until 1681, when an order was issued forbidding the feeding of swine within the city limits. The Germans are said to have introduced privies at an earlier date than the French ordinances referred to, as mention of them is made in the annals of Frankfort-on-the-Maine in 1477.

Mr. Beckmann wrote in 1846, and the account he gave of the sanitary conveniences of Berlin, at that date, will surprise some readers. He says that in most of the houses small closets are located on the landings of the stairs, which must be emptied every other night with most unpleasant consequences. In the streets, large puddles of filth were allowed to collect even before the doors of the best houses, and in the summer these puddles emitted "a horrible stench." While the streets were spacious and straight and fairly well paved with flagstone, the footways were divided from the carriage drive by open kennels, "telling the nose unutterable things." Our author closes by remarking of this city that, "If bronze and marble could smell, Blucher and Bulow, Schwerin and Liethen, and duck-winged angels and two-headed eagles unnumerable, would be found on their pedestals, holding their noses instead of grasping their swords."

◆

THE SUM OF $100,000 FOR SLUDGE DISPOSAL at Worcester, Mass., was appropriated a few days ago by the city council. Since the sewage precipitation plant was put in operation at Worcester in 1890, the sludge has been spread on beds to dry, or partially dry. Its final disposition has been more or less troublesome from the start. It is now proposed to put in a pressing plant, by means of which a large percentage of the moisture will be removed.

◆

A CHEMICAL LABORATORY FOR THE STREET Department of Brooklyn, N. Y., has recently been established for use in connection with asphalt paving work. It is in charge of Mr. W. Homer Broadhurst, a graduate of the Brooklyn Polytechnic in 1894.

◆

THROUGH TRAINS ACROSS THE BROOKLYN Bridge are again being urged by President Ullman of the Brooklyn elevated railways. At the meeting of the bridge trustees, on July 13, he presented a report by Mr. Geo. B. Cornell, M. Am. Soc. C. E., answering the objections presented by Messrs. Martin and Leverich of the bridge staff to the operation of through trains.

◆

A CRITICISM OF THE DESIGN accepted by the Commissioners of Fairmount Park for the new bridge over the Schyylkill River, and shown on p. 13 of our issue of July 2, has been presented to the commissioners by Mr. Percival Roberts, Jr., M. Am. Soc. C. E. Mr. Roberts urges that the bridge should contain three arches instead of four; that the masonry of the piers should be carried to the level of the roadway, and that as the roadway has a 1.2% grade, the arches will be out of the horizontal and will look badly if constructed according to the accepted design. He also claims that the design is for a lighter structure than that called for by the specifications of the chief engineer.

◆

SHIP BUILDING IN THE UNITED STATES was fairly active during the year ending June 30, 1896, according to statistics just issued by the Bureau of Navigation. There were 709 vessels of 204,000 gross tons built, against 682 vessels of 133,000 tons in the previous year. There were 322 steam vessels built of 135,000 tons, against 283 of 75,700 tons in the preceding year. The tonnage of steel vessels built was 106,900 against 47,700 in the previous year. On the Great Lakes 104 vessels of 92,000 tons were built as compared with 93 vessels of 38,000 tons in the year preceding.

◆

THE BOSTON PNEUMATIC TRANSIT CO. is seeking a charter for a general system of pneumatic delivery pipes in the streets of Boston, and is to have a hearing before the Board of Aldermen July 20. A similar charter was applied for a year ago, and was granted by the Aldermen, but was vetoed by the Mayor.

PROPOSED EXTENSIONS TO THE MANHATTAN Elevated system were outlined at a meeting of the New York Rapid Transit Commission on July 16, by the President, Geo. Gould. It was proposed to build surface trolley roads along the streets of the annexed district, with an agreement to build elevated lines in their place whenever the earnings would pay the interest on the cost of an elevated structure. It was stipulated, however, that the Manhattan Ry. Co. must be protected against substantially all claims for damages on the part of owners of abutting property. Under the law the Rapid Transit Commission would have no power to grant guarantees of this sort nor, in fact have they any power to grant franchises for surface railways at all. No action was taken upon the application by the Commission, nor does any action appear likely at present.

A NEW RAPID TRANSIT ROUTE was proposed by Chief Engineer W. B. Parsons at the above meeting, which it is believed could be built under the authority granted to the previous commission, provided the legislature amended the present law which makes obligatory the construction of the road by the city. The proposed system would comprise a four-track road from City Hall Park to 42d St., and an east side and west side branch, each of two tracks, extending to the Harlem River and 135th St., respectively, with elevated railway extensions from these points north. The estimated cost of such a system on the basis of the unit prices approved by the Board of Experts some years ago would be $21,000,000, or adding 20% to 40% for contingencies on the various items, $26,500,000. One mile sections of third track on these branches north of 42d St. would be included to permit the running of express trains. The proposal will be considered at a meeting of the Commission July 30.

A TUNNEL UNDER UNION SQUARE, New York city, is proposed by the Metropolitan Street Ry. Co. to eliminate the dangerous curve at 14th St. The tunnel would be about 520 ft. in length with masonry portals of ornate design. It would be roofed with iron beams and lined with enameled bricks, and its cost is estimated at $150,000 to $200,000. Consent to the construction of such a tunnel is doubtful, as it would interfere with the construction of a rapid transit railway on the Broadway route. If its construction is not permitted, the Metropolitan Traction Co. will put in a special slow cable to haul its cars around the 14th St. curve. The experiments now in progress with compressed air motors may also lead to an entire change of motive power, though this is considered hardly probable.

DANGERS OF FIXED POSTS NEAR MOVING CARS are illustrated by a column of the Kings Co. Elevated Ry. on Fulton St., Brooklyn, which is said to have injured 20 men during the past few months. The course of the cars is now to be changed to pass it on the other side.

AN ELECTRIC LOCOMOTIVE of 75 tons weight is to be built jointly by the Baldwin Locomotive Works and the Westinghouse Co., and will use the Wheless current collecting system controlled by the Westinghouse Co. In this system there is neither an overhead wire nor a conduit, the current is led to contact boxes projecting ⅝-in. above the pavement, and an electro-magnetic device on the car switches the current onto each box as the car passes over it. At all other times the boxes are dead. The 30-ton electric locomotive exhibited at Chicago in 1893 by the General Electric Co. has been purchased by the Manufacturers' Street Ry. Co., of New Haven, Conn., to haul freight cars from Cedar Hill, a point on the main line of the New York, New Haven & Hartford R. R., one mile from the New Haven passenger depot, to the works of the Bigelow Co., the National Pipe Bending Co., and other large manufacturers. The total length of the branch is nearly two miles, and the maximum grade 2½%. The locomotive has a rated draw-bar pull of 7,000 lbs.

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred July 15, at Quincy, Ill., on the Chicago, Burlington & Quincy Ry. It was a head collision between a switch engine and freight train. Two men of the engine crews were killed and two injured, one fatally. Both locomotives were demolished. On July 16, near Littleton, N. H., a logging train consisting of locomotive and three loaded cars ran away on a grade of 400 ft. to the mile; on rounding a 10° curve the cars left the main track and ran onto a siding. Two persons were killed by jumping and two were injured. An account has been received of an accident on the Jamaica Ry. which occurred July 11, about ten miles from Anato Bay. A locomotive with six flat cars loaded with laborers was descending a steep mountain grade when the air brakes failed. The train kept the track but ran into a locomotive at the bottom of the grade; 17 persons are reported killed and 33 injured.

THE OVER-CROWDING OF TROLLEY CARS in Brooklyn, N. Y., still continues, notwithstanding the orders of the Chief of Police. On July 19 a crowded car on the Nassau line while making up time, left the track at a curve and ran into the ditch. Seven persons were injured, the conductor seriously. President A. L. Johnson is quoted as saying that there have been 2,400 trolley accidents in Brooklyn since last April.

A SODA FOUNTAIN TANK EXPLODED, July 15, in the factory at 331 East 26th St., New York city. One man was killed and two injured; 25 tanks were being charged by an automatic filling device. The tanks are of iron and the pressure used is 150 lbs.

A WOODEN HIGHWAY BRIDGE, at Canton, O., collapsed July 13. Two men with a traction engine attempted to cross, the failure occurring when the engine was at the middle of the bridge. One man was killed and the other injured.

A FALLING WATER TANK wrecked a six-story brick building at 241 Jefferson St., Chicago, July 11. The tank was located on the roof. It contained 5,000 gallons of water and fell through to the basement. The damage to the building is estimated at $7,900.

BOILER EXPLOSIONS in Great Britain during 1895 numbered 44, according to the records kept by the Manchester Steam Users' Association. In these explosions 40 persons were killed and 54 were injured. Of these explosions 29, killing 36 persons and injuring 43, were steam boiler explosions proper, while the remainder were explosions of steam pipes, heaters, kiers, etc. Only one of these explosions was of a boiler insured in the Association, and this was of trivial importance, being merely a steam launch boiler, which fractured the neck of a cast-iron chest to which the safety-valves were attached. The fracture was due to the use of the vessel as a ram to crush ice in the Manchester ship canal.

AN AMERICAN LOCOMOTIVE BUILDING PLANT is to be erected at Nijni-Novgorod, Russia, by a corporation known as the Russian-American Manufacturing Co. Mr. H. H. Hollister, of New York city, is the President of the company, Mr. E. D. Smith, of Philadelphia, is the Vice-President, and Mr. W. F. Dixon, late chief draftsman of the Rogers Locomotive Works, at Paterson, is the General Manager. The works are to be built adjacent to the Sormovo works, a large manufacturing establishment about five miles from the town of Nijni-Novgorod. Contracts for machinery for their equipment to the value of about half a million dollars have already been placed with the principal American builders of machine tools. Five buildings are being erected, from designs made by Mr. Dixon, assisted by Julian Kennedy, M. Am. Soc. M. E., of Pittsburg, and are expected to be completed this fall, and it is intended to have the shop equipment completed and ready for use by the following spring. The works are designed for an output of about 150 locomotives per annum and will employ about 1,000 men. Besides Mr. Dixon, who will have the general management of the works and an assistant, the foremen of the various departments and some of the draftsmen will be Americans, about a dozen men in all will be engaged. We are indebted for the above information to our contemporary "The Railroad Gazette."

THE GREAT SIBERIAN RAILWAY is now completed to Krasnoyarsk. During the season of 1895, 918¼ miles were built. This gives a direct route from Petersburg to the Yenesei River, a distance of 3,056½ miles. The proposed length of the Great Siberian Ry. from Cliuliabinsk to Vladivostok on the Japan Sea is 4,547 miles, of which more than one-third is now completed. A large amount of work has also been done on the branches. There are now engaged upon the actual work of construction over 70,000 workmen, beside engineers and officers. Up to 1896 $32,488,000 had been expended. The plan of building across the mountains and canyons on the south of Lake Baikal, which was the most difficult feature of the whole enterprise, has been abandoned and trains will be ferried across the lake, by transfer steamers, a distance of about 20 miles.

THE IMPROVEMENT OF NAVIGATION at the Iron Gates of the Danube has been practically completed and is to be celebrated with appropriate ceremonies in connection with the thousandth anniversary of the foundation of Hungary next month. The inauguration ceremonies are to be held at Orsova, and will be attended by the sovereigns of Austria, Germany, Roumania, Servia, Bavaria and Bulgaria. The work has been in progress about five years and was described in our issues of July 11, 1891, and April 2, 1892.

THE GREAT U. S. LOCK at Sault Ste. Marie is expected to be ready for the passage of boats early next month.

NOTICE TO STOP POLLUTING THE CANISTEO River has been served upon Hornellsville, N. Y., by the town of Canisteo. The notice declares the discharge of sewage into the river by Hornellsville a nuisance.

LEGAL STEPS TO PREVENT THE DISCHARGE OF coal dust into the Schuylkill River have been taken in the name of the attorney general of Pennsylvania and the city of Philadelphia. Complaint is entered and injunctions asked against the Philadelphia & Reading Coal & Iron Co., the Lehigh Coal & Navigation Co., and four other companies. The bill alleges that the trouble arises from washing the coal as it comes from the breakers and also from washing culm from old banks. The protection of the water supply of Philadelphia is the main object of the action.

THE FILTER BEDS CONNECTED WITH THE WATER supply of Poughkeepsie, N, Y., are being enlarged by adding an area of ⅔ acre. The present beds were built with the water-works some 25 years ago, and have an area of 0.675 acre.

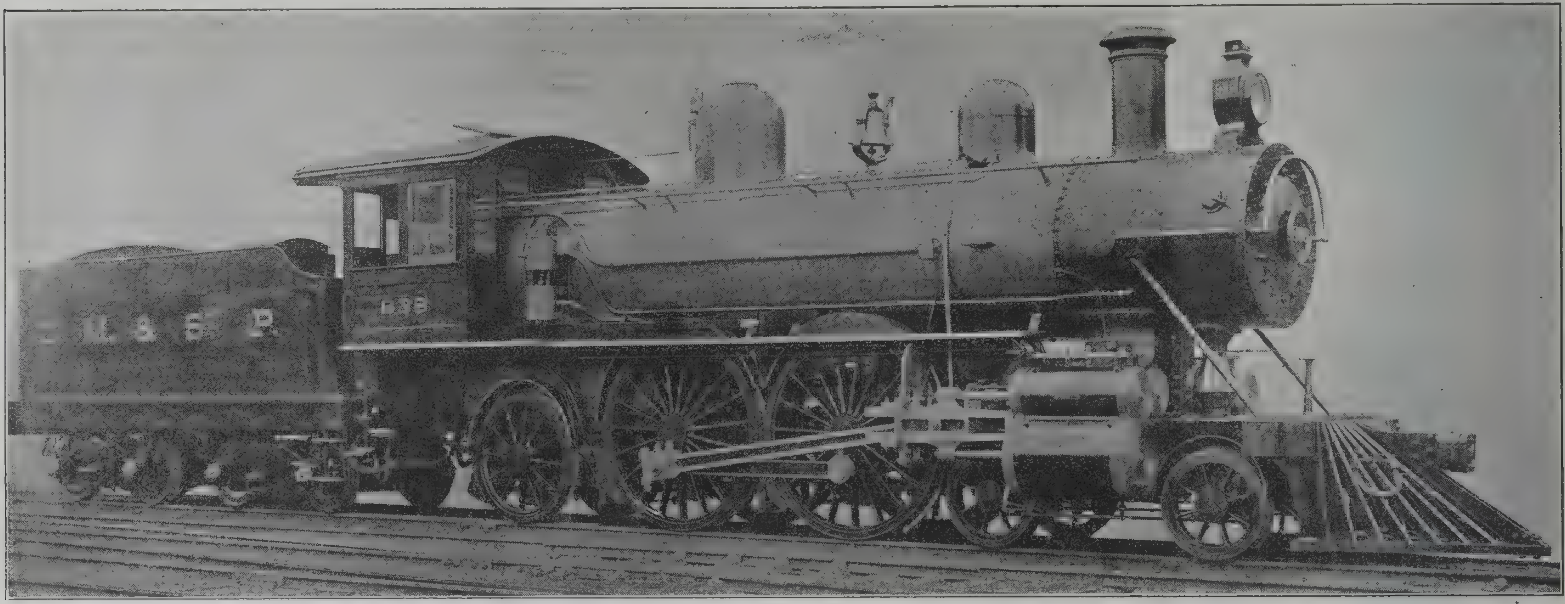
A SINGLE 48-IN. CAST-IRON MAIN has been recommended for the new water supply conduit for Brooklyn rather than the acceptance of either the bid for a double line of 48-in. cast-iron pipe or a single line of 66-in. steel. This recommendation has been made by both Mr. I. M. de Varona, M. Am. Soc. C. E., Engineer in charge of the Water-Works, and Mr. Peter Milne, Chief Engineer of the Department of City Works. Both of these gentlemen base their decision on uncertainties connected with the future water supply of the city and the additional cost of the steel conduit. Of course the steel conduit is the cheaper of the two, carrying capacity considered, but Mr. de Varona urges that the city is near the limit of its bonded indebtedness. The final decision of the matter rests with Mr. Theo. Willis, Commissioner of City Works, who is reported as favoring the steel, or larger main, since it can be secured at $780,000 with asphalt, and $802,000 with Sabine coating, against $677,000 for the cast-iron pipe.

THE LOWEST BID FOR TWO 48-IN. CAST-IRON water mains on Fifth Ave., New York, from 4th to 80th St., a distance of about 3¾ miles, was $452,460. This bid was made by Mr. Wm. T. Baird, of New York. There were nine other bidders. Details of the bids will be published in our next issue.

WATER POWER to the amount of 10,000 HP. is being developed at Columbia, S. C., by the Columbia Water Power Co., a concern backed by New England capital. Aretas Blood, of Manchester, N. H., well known in railway circles in connection with the old Manchester Locomotive Works, is the President; A. F. Sortwell, of Cambridge, Mass., President of the Montpelier & Wells River R. R., is Vice-President, and W. M. Upham, of Baltimore, is Secretary. The power is being developed from a water-power canal which was begun many years ago by the state of South Carolina, and was recently turned over to the city of Columbia. The power-house, 184 × 31 ft., is being built by W. A. Chapman & Co., of Providence, R. I. It will contain eight pairs of 51-in. McCormick turbines, built by the Rodney-Hunt Machine Co., of Orange, Mass., and eight large generators built by the General Electric Co. The work is expected to be completed by Oct. 1. The water-power company proposes to sell its power at $15 per HP. per annum delivered anywhere in Columbia, the above price being for units of not less than 500 HP. used 66 hours per week.

BALDWIN COMPOUND LOCOMOTIVE FOR FAST PASSENGER SERVICE; C. M. & ST. P. RY.

The Baldwin Locomotive Works has recently delivered to the Chicago, Milwaukee & St. Paul Ry., two large compound locomotives designed for fast passenger service. The accompanying illustration is reproduced from a photograph of one of these engines, for which we are indebted to the courtesy of the builders.



FOUR-CYLINDER COMPOUND LOCOMOTIVE FOR FAST PASSENGER SERVICE, CHICAGO, MILWAUKEE & ST. PAUL RY.
Baldwin Locomotive Works, Builders. J. N. Barr, Supt. of Motive Power, C., M. & St. P. Ry.

The locomotive is of the "Columbia" type with a trailing pony truck in the rear of the drivers, a design originated by the Baldwin Works in 1893 and used since on the Philadelphia & Reading, Chicago, Burlington & Quincy and other railways. The principal dimensions are as follows:

Gage of road	4 ft. 8½ ins.
Cylinder, diameters	h.-p., 13 ins.; l.-p., 22 “
Stroke	26 “
Driving wheels, diameter	78 “
Total wheel base	25 ft. 6 “
Rigid wheel base	13 “ 9 “
Driving wheel base	6 “ 9 “
Weight, total	140,700 lbs.
“ on drivers	71,600 “
“ on trailing wheels	29,100 “
“ on trucks	40,000 “
Boiler diameter	60 ins.
No. of tubes	264
Diameter of tubes	2 ins.
Length of tubes	15 ft.
Firebox length	103 3-16 ins.
Firebox width	42⅛ “
Firebox depth	front, 71½ ins.; back, 69 ins.
Heating surface, firebox	171.0 sq. ft.
“ “ tubes	2,073.5 “ “
“ “ total	2,244.5 “ “
Truck wheels, diameter	36 ins.
“ journals	5½ × 10 “
Trailing wheels, diameter	54 “
“ journals	7 × 12 “
Tender tank capacity	4,500 gallons
“ wheels, diameter	33 ins.
“ journals	4½ × 8 “

On July 3, this locomotive hauled a train of 14 cars from Chicago to Milwaukee in 115 minutes, the distance being 85 miles. The train consisted of 4 baggage and express cars, 4 day coaches, 4 drawing room cars and 2 sleeping cars. The total weight hauled by the locomotive was estimated at 1,000,000 lbs. The train made two stops, at Western Union Junction and National Ave., and had a delay of five minutes at the first, which was made up in the next eight miles of the run, the train speed reaching at times, it is claimed 80 miles per hour. On another trip over the same run with 11 cars, one of which was the private car of Jos. Barker, General Passenger Agent of the Missouri, Kansas & Gulf R. R., a speed indicator on that car is said to have shown a speed of 77 miles per hour.

◆

RULES FOR LOADING LONG STRUCTURAL MATERIAL ON RAILWAY CARS.

The Master Car Builders' Association at its recent meeting at Saratoga appointed a committee to report a set of rules for loading long lumber and timber, and also to govern the loading and carrying of long structural material such as plates, rails, beams, girders, trusses etc. The report of this committee has just been submitted to letter ballot for adoption, as the practice recommended by the Association for use on all railways. It is altogether probable that the letter ballot will result favorably, and that all railways will require shippers of long timber and structural material to conform to these rules. We reprint herewith in full the rules for loading structural material. As the rules for loading long timber are still more voluminous and contain several large tables, we do not reprint them, but any of our readers desiring copies of these rules can obtain them of the Secretary of the Association, Mr. John W. Cloud, Rookery Building, Chicago, after the result of the letter ballot is ascertained.

General Instructions.

1. On account of the great variety of form and weight of long structural material, no general rules can be made to suit all cases. The following regulations are, therefore, intended to cover only the most common forms. When material cannot be loaded in accordance with these regulations, special instructions must be asked for.

2. Cars to be used for shipments of this character must be carefully examined before loading, and all defects must be remedied before the cars are loaded. Great care must be taken not to overload cars, and in the case of very long or very heavy material the truss rods should be screwed up tight. The weight of the lading carried on any car must be governed not only by the marked capacity of the car, but also by its general construction, as well as by the number and location of the bearing pieces upon which the load rests. The regulations covering these points are given in Detail Instructions for each form of loading, and must be strictly adhered to. The only exceptions are cars which have been specially prepared for the shipment of particular forms of material.

3. Material over forty feet long carried on two or three cars must always be examined by a competent inspector before the cars are moved from the loading point. If no inspector is stationed at the loading point, the local agent must give notice to the proper authority when the cars are loaded, so that proper inspection can be arranged for. The object of such inspection is to see that these regulations have been complied with.

4. Standing room of at least 18 ins. must always be left around brake shaft at one end of the car to permit the proper operation of the brake, and at the other end of the car, when a single car is used, the lading must not project beyond the end sill, except in the following case: When the lading is too long to go inside the car, but will not extend more than 6 ins. beyond the end sill, such method of loading will be permitted, providing the projecting ends of the material will clear 6 ft. 6 ins. above the rail.

5. In all other cases when the lading extends beyond the end sill of the car, an idler must be used or the material must be loaded on two or three cars, as the case may demand, and as explained under Detail Instructions below.

6. Long iron, rails, bridge material, channels, angle irons, etc., should, whenever possible, be loaded on single gondola cars inside the end gates, which must in all cases be raised and securely fastened. Single flat cars must not be used for rails or bar iron, unless furnished with substantial end boards to prevent shifting of the load.

7. Whenever the lading is carried by more than one car, all slack between cars must be removed by the use of spacing blocks in the manner described in Detail Instructions. Cars must also be chained together in order to prevent parting in case of failure of the couplings. When cars are used which are not permanently equipped with safety chains, chains made of not less than ¾ in. iron must be passed around the body bolsters and across under sills, forming a loop back of bolster and doubling to point of coupling between the two cars, and so tie them together. These long chains must only have a sufficient amount of slack to permit the cars to curve. At interchange points chains will either be removed, or the receiving road will furnish the delivering road with chains of the same quality and dimensions as those received.

8. When either one or two bearing pieces are required, they must never be placed between the bolster and the end of the car, but either between the bolsters or directly above the bolsters. When only one bearing piece is used on a car, as in Figs. 13 and 14, it must be placed at a distance of at least 12 ins. from center of bolster toward center of car.

9. All spacing blocks between cars, bearing pieces, spacing blocks between material, clamping pieces, bolsters and all braces must be of hard wood and sound in every way. Dimensions given are, however, intended to be general only, and any material that may be suitable for blocking, but which differs in dimensions from figures given, but which is of equal strength or stronger, may be utilized.

10. Height and width of lading must be governed by tunnel and bridge limits of roads over which lading is destined.

11. When two or three cars are used, cars carrying load must be considered of the same capacity as the one of lesser capacity.

Detail Instructions.

Loading of Single Cars Without Idlers.

12. Large girders loaded on flat side on flat cars must always be carried upon bearing blocks not less than 4 × 12 ins., which must be placed one over each bolster and secured to the floor with two ⅞-in. bolts. When two or more large girders are carried on a flat car, the bearing blocks must not be less than 6 × 12 ins., and fastened in the same manner to the floor. In addition, spacing blocks not less than 3 × 12 ins. must be placed between each girder. Lateral motion must be prevented by means of upright iron stanchions, driven into holes in the bearing pieces and held together at the top by not less than 2 × 6 in. planks, as shown in Fig. 2, or it may be prevented by fitting planks between flanges of the girders, as shown in Fig. 3. To prevent longitudinal motion, angle plates, 5 or 6 ins. wide by ½ in. thick, must be bolted firmly to the lower girders close to the bearing pieces, as shown in Fig. 1, or if rivet holes are not available, it may be prevented by clamps, as shown in Fig. 4. The upper girder must be held to the lower girder by diagonal flat-iron braces bolted to both girders, as shown in Fig. 1. If, however, girders are clamped together, as shown in Fig. 4, the diagonal flat-iron braces need not be applied.

Loading of Single Cars With Idlers.

13. When the lading is too long to go inside of a car and extends more than 6 ins. beyond the end sill, such loading will be permitted if an idler or idlers are provided to protect the overhanging part of the loads, as in Figs. 5, 6 and 8; but in these cases the length of the permissible overhang must be governed by the width of the lading and its height above the rail, and it must in no case exceed the figures given below, which are based on clearance required on a 20° curve, it being understood that the

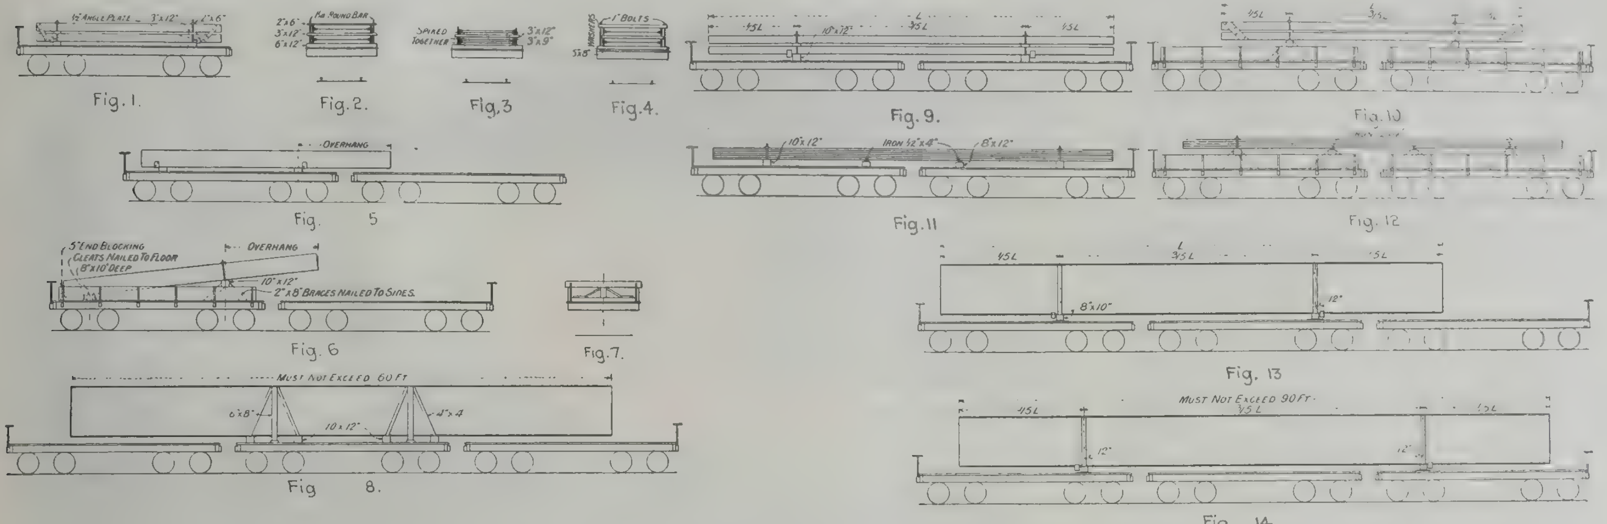
load must be placed centrally on the car and the amount of overhang measured from center of bolster on the carrying car.

For loading in accordance with Figs. 5, 6 and 8:

8 ft. wide	10 ft. overhang.
7 ft. wide	14 ft. overhang.
6 ft. wide, or less	18 ft. overhang.

14. To prevent overloading of the truck under the overhanging end, as shown in Figs. 5 and 6, the carrying capacity of the car will decrease in the following manner as the length of the overhanging increases:

For overhang not exceeding 5 ft., car may carry full marked capacity; for overhang not exceeding 10 ft., car may carry three-fourths of the marked capacity; for overhang greater than 10 ft., car may carry one-half the marked capacity.

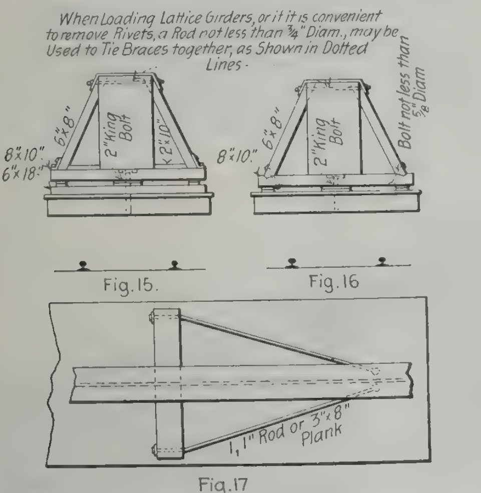


FIGS. 1 TO 14.—METHODS FOR LOADING STRUCTURAL MATERIAL ON CARS PROPOSED FOR ADOPTION BY THE MASTER CAR BUILDERS' ASSOCIATION.

15. (a) The idlers used with loads as shown in Figs. 5 and 8 must be flat cars, unless the width of the overhanging part of the lading is at least 3 ft. less than the width given for each length of overhang in the table in paragraph 13, in which case drop-end gondola cars may be used.

(b) The idler used with loads as shown in Fig. 6 may be a low-side gondola car, but must not be a high-side gondola car.

16. The idlers may be loaded with any suitable material, provided the consignee and the destination of the material on all the cars are the same. There must be, however, a space of at least 2 ft. between ladings on the carrying car and on the idler. The carrying capacity of the idler depends upon how far the overhang extends over the idler, and must not exceed the following figures, except with ladings as in Fig. 6, in which the overhang may be so far above the floor of the idler as not to interfere with its lading. In such cases the idler may carry full marked capacity:



When Loading Lattice Girders, or if it is convenient to remove Rivets, a Rod not less than ¾" Diam., may be Used to Tie Braces together, as Shown in Dotted Lines.
6"x8"
2" King Bolt
2"x10"
8"x10"
6"x18"

1, 1" Rod or 3"x8" Plank
Fig. 17

Figs. 15 to 17.—Swivelling Bolsters for Supporting Long Girders.

When overhang does not extend over idler more than 5 ft., full marked capacity; when overhang does not extend over idler more than 10 ft., three-fourths of the marked capacity; when overhang extends over idler more than 10 ft., one-half of the marked capacity.

17. When large girders are loaded, as shown in Fig 5, they must be secured to carrying car, as explained in paragraph 12.

18. When material is loaded on gondola cars and is longer than the body of the car, as shown in Fig. 6, one end must rest on a bearing piece not less than 10 × 8 ins., placed on the floor above the bolster and extending the width of the car. It must in all cases be of sufficient depth to prevent the lading at this end from touching the floor of the car. It must be secured from shifting by cleats nailed to the floor. The end boards at this end of of the car must be protected by blocking not less than 5 ins. thick, fitted snugly between the side boards and extending upward to a height sufficient to prevent all parts of the load from touching the end boards of the car. The other end of the load must rest upon a bearing piece, square or round, preferably square, not less than 8 × 10 ins. if square cornered, nor less than 10 ins. in diameter if round. This bearing piece must rest upon the side boards of the car directly above the bolster, and it must be securely braced to prevent both lateral and longitudinal motion, and if round it must also be braced against rolling; it must also be supported from bending. Figs. 6 and 7 show substantially how both bearing pieces are to be secured. To prevent the load from shifting in a lateral direction on the bearing piece, iron stanchions tied together with a plank at their upper ends must be used as described in paragraph 12.

19. A method of loading especially adapted to long lattice girders, which may be injured if loaded on more than one car, is shown in Fig. 8. For loads of this character four bearing pieces must be placed in pairs on the carrying car each pair being placed centrally above the bolster, with a distance apart of not over 5 ft. nor less than 3 ft.; they must be fastened to the floor with bolts, as explained in paragraph 12, and the upright supports must have side braces. Braces or tie-rods must be secured to the overhanging ends and to the bearing pieces, as shown in Fig. 17. Longitudinal motion must be prevented by the use of plates or clamps, as explained in paragraph 12.

Loading of Two or Three Cars With or Without Idlers.

20. Material which in length exceeds the limits given for the loading of one car must be loaded on two or three cars, as shown in Figs. 9, 10, 11, 12, 13, 14. 15 and 16. With loads of this character the lading must never exceed maximums given in paragraph 26. The carrying cars must always have all slack between them removed by the use of spacing blocks, as described in detail in paragraph 28, and the cars must be chained together, as explained in General Instructions, paragraph 7.

21. Material loaded on gondola cars with drop ends or open ends or on flat cars, as shown in Fig. 9, must have one bearing piece not less than 10 ins. wide by 12 ins. deep secured to the floor of each car with two ⅞-in. bolts. Lateral and longitudinal motions must be prevented in the manner described in paragraph 12. In the case of gondola cars, a clearance of at least 18 ins. between the load and car sides must always be provided for curving.

22. Material loaded on gondola cars without drop end doors, as shown in Figs. 10 and 12, must have bearing pieces placed on the top of the side boards, of the same size and secured in the same manner as described in paragraph 18. The lading must be secured from lateral and longitudinal motions as described in paragraph 12.

23. Long flexible material, like plates, etc., must be loaded on four bearing pieces, as shown in Figs. 11 and 12. The two center bearing pieces must, however, be 2 ins. lower than the end pieces and have the flat iron ½ × 4 ins. secured on their upper side, either with spikes having countersunk heads or with two ½-in. lag-screws at each end; these iron pieces, which are intended to facilitate curving, must extend at least 1 ft. beyond each side of the lading and must be coated with grease. The bearing pieces must be secured to the car, and the material clamped together to prevent it from shifting, in the manner described in paragraphs 12 and 18. If loaded in gondola cars with drop end doors, the same clearance must be provided between the lading and car sides as specified in paragraph 21.*

24. Large girders loaded on edge, as shown in Figs. 13, 14, 15 and 16, on two or three cars, either with or without idler, must be supported on two swiveling bolsters, which may be constructed either as a double bolster (Fig. 15) or a single bolster (Fig. 16). The double bolster is preferable for wide and heavy loads on account of the better distribution of the load over the car stringers, and must always be used when the width of the lading exceeds 3 ft. or its weight exceeds one-half the marked capacity of the car. Deep girders which cannot be loaded on double bolsters without exceeding the limit in height in paragraph 13, and low girders less than 3 ft. wide, may be loaded on single bolsters, provided that the weight carried by each car does not exceed one-half of its marked capacity. When double bolsters are used, the lower piece must be securely fastened to the car floor, as described in paragraph 12, and must be not less than 6 ins. deep by 18 ins. wide. King bolts, center bearings and side bearings must be used for either kind of bolster and both center bearings and side bearings for the upper bolster must move on corresponding bearings, secured either to the lower bolster or to the floor of the car, as the case may be. When wrought iron plates are used for side bearings with single bolsters, the lower plate must be fastened to the car floor with countersunk screws or with two lag-screws at each end placed at least 12 ins. away from sides of bolsters. The girders must also be secured to the upper bolster with diagonal tie-rods or braces, as shown in Fig. 17; if braces are used they must not be less than 3 × 8 ins. Diagonal side braces must be used between the top flange of the girder and the outer ends of the top bolster, as shown in Figs 15 and 16. When the lading consists of two or more girders standing side by side or lying on their sides, they must be securely fastened to each other as described in paragraph 12.

Figs. 18 to 21.—Methods for Blocking Cars Apart.

25. The location of the bolsters depends upon the length and width of the girders, as well as upon their stability, and they should, if possible, be so placed that the length

---

*If more than four bearing places are required to properly support the lading, the center pieces on each car must be provided with upright stanchions, as in paragraph 12.

of each overhanging end is not more than one-fifth, and the distance between the bolsters not less than three-fifths, of the total length of the girder. The following table gives locations of bolsters for girders of maximum length and width, based on clearance required on a 20° curve:

60 × 8 ft., or less, bolsters not less than 36 ft. bet. centers
70 × 7¼ ft., or less, bolsters not less than 42 ft. bet. centers
80 × 6½ ft., or less, bolsters not less than 48 ft. bet. centers
90 × 5½ ft., or less, bolsters not less than 54 ft, bet. centers

In case of material of less width than 5½ ft. but of greater length than 90 ft., applications must be made to the proper authority for special instructions.

26. To prevent overloading the following regulations must be adhered to:

(a) When only one bearing piece is used and its location is near the center of the car, as in Fig. 9. Flat cars having only two truss rods, weight of lading must not exceed one-half of marked capacity of car. Flat cars having more than two truss rods, and low side gondola cars, weight of lading must not exceed two-thirds of the marked capacity of car.

(b) When only one bearing piece is used and it is located about equal distance from center of car and center of truck, as on end car in Fig. 13. Flat cars having only two truss rods, weight of lading must not exceed two-thirds of marked capacity of car. Flat cars having more than two truss rods, also low-side gondola cars, weight of lading must not exceed three-fourths of marked capacity of car.

(c) When only one bearing piece is used, and it is located at or near the center of the truck, as on center car in Fig. 13, and on end car in Fig. 14, or on top of sides on high-side gondola cars in Fig. 10, the weight of the lading must not exceed one-half of the marked capacity of the car.

(d) When more than one bearing piece is used on each car as in Figs. 11 and 12. Flat cars and low-side gondola cars, weight of lading may equal marked capacity of car. High-side gondola cars, weight of lading must not exceed three-fourths of marked capacity of car.

27. The selection of cars to be used as idlers with loads, as shown in Figs. 13 and 14, must be governed by paragraph 15 (a).

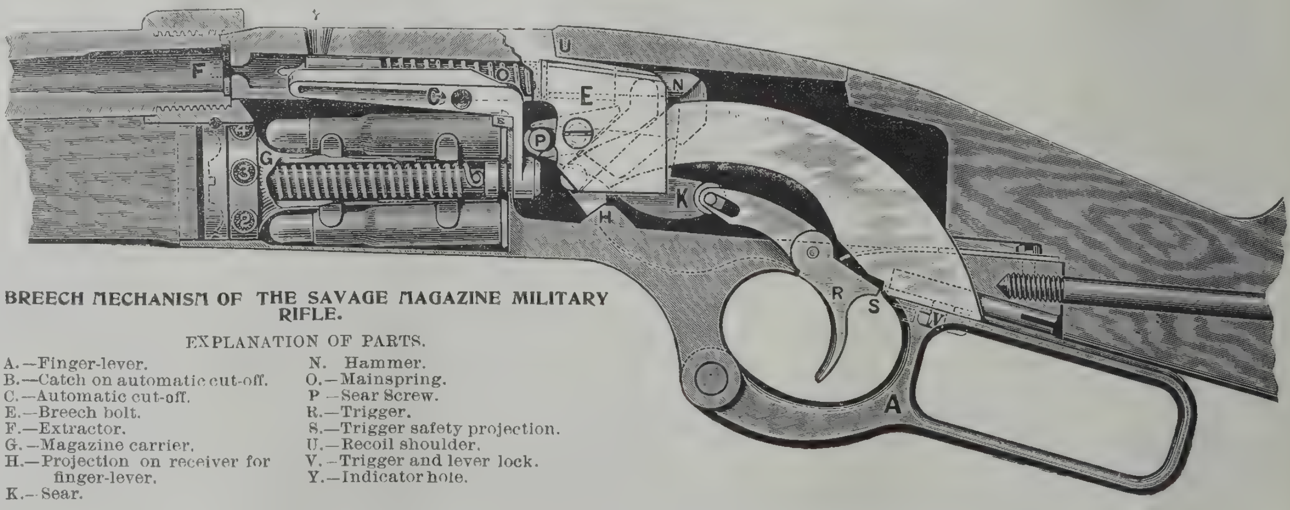
28. The method of blocking cars apart, to be used when a load is carried on two adjacent cars, or when it is carried on two cars separated by an idler, is shown in Figs. 18 and 21, inclusive. Figs. 18 and 19 represent both the cars with ordinary drawheads. Fig 20 represents one car with M. C. B. coupler and the other car with ordinary drawhead. Fig. 21 represents both cars with M. C. B. couplers. In blocking cars apart they must first be separated by means of jacks until all the slack in the springs, couplers or links, if the latter are used, has been taken up; the spacing blocks must then be neatly fitted between the cars and secured in the manner shown. All wood used must be sound oak.

◆

THE NEW RIFLE FOR THE NEW YORK MILITIA.

We show in the accompanying cut the breech mechanism of the Savage military rifle, which, as we stated last week, has just been selected by an able commission appointed to recommend an arm for the use of the New York State Militia. Twelve guns were submitted to the Commission for examination and tests, including such well-known weapons as the Lee and Winchester rifles. In reporting its decision the Commission gave the following high praise to the Savage gun:

> The Savage magazine rifle, lever action, magazine holding five cartridges, in strength and fineness of parts, very close compliance with the eleven "salient points" mentioned in the instructions for the consideration of the Board by the Adjutant-General, ease of manipulation and general all-round excellence, won the unanimous decision of the Board of Examiners as being clearly the best military magazine rifle submitted for their examination. We feel confident that with the Savage magazine rifle placed in the hands of the National Guard of the State of New York, a new life will be imparted to the art of target practice, great pride in the accuracy and beauty of the arm developed, and the very best weapon in the world for military purposes secured for their use.



BREECH MECHANISM OF THE SAVAGE MAGAZINE MILITARY RIFLE.

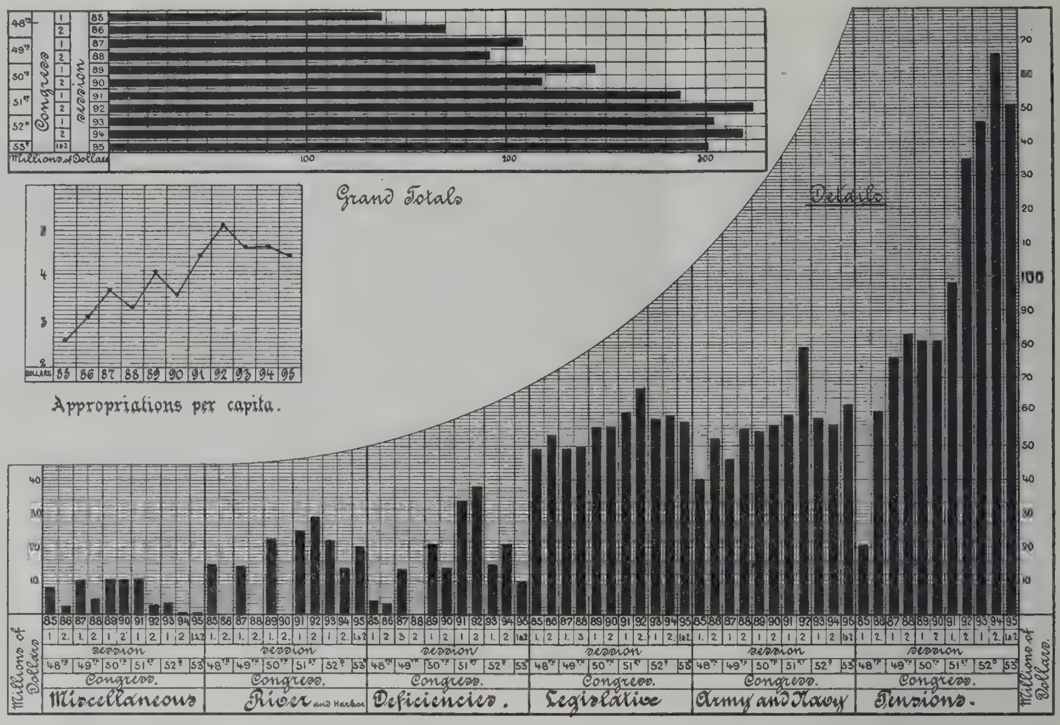
EXPLANATION OF PARTS.

A.—Finger-lever.
B.—Catch on automatic cut-off.
C.—Automatic cut-off.
E.—Breech bolt.
F.—Extractor.
G.—Magazine carrier.
H.—Projection on receiver for finger-lever.
K.—Sear.
N. Hammer.
O.—Mainspring.
P —Sear Screw.
R.—Trigger.
S.—Trigger safety projection.
U.—Recoil shoulder.
V.—Trigger and lever lock.
Y.—Indicator hole.

Our readers familiar with small arms will, we presume, be able to understand the construction of the Savage gun from the accompanying drawing, which shows the lever closed. The gun can be used either as a single loader or a magazine rifle as desired. Throwing down the lever opens the breech and permits the insertion of the cartridge directly into the chamber, when the gun is used as a single loader. The lever is then pulled up, forcing the cartridge home, closing the breech and cocking the firing pin. The trigger cannot be pulled to release the firing pin until the lever is forced to its seat and the breech is entirely closed. After the piece is fired the lever is pushed down, which extracts the empty shell and throws it to the right.

The magazine arrangement is remarkably compact and simple. The bulge or protuberance below the stock, which has been a feature of most magazine rifles, has been eliminated. An index shows at a glance the number of cartridges in the magazine. For military use it is believed that a magazine containing a small number of cartridges is better than one with a large number as with the former the soldier will not be as likely to waste his stock of ammunition.

The gun is made by the Savage Arms Co., of Utica, N. Y., to whom we are indebted for the illustrations given herewith.



APPROPRIATIONS MADE BY CONGRESS FOR THE FISCAL YEARS, 1885 TO 1895.

◆

THE EXPENDITURES OF THE UNITED STATES IN ELEVEN YEARS.

We believe that most of our readers will be interested in an examination of the accompanying diagram, which we reproduce from a recent publication of the Bureau of Statistics of the Treasury Department. It shows at a glance the increase in national expenditures from $140,000,000 in 1885 to over $280,000,000 in 1891; and also the fact that since 1892 this increase has been very properly checked, although there are no signs that the total outlay or the expenditure per capita will be reduced to where it was in the early 80's.

The most interesting part of the diagram is that which shows the amount of the appropriations for different purposes. Unfortunately, the distribution is not complete, there being no means of telling, for example, to what the "deficiency" or the "miscellaneuos" appropriations are applied. The different colors which in the original showed the proportion of the Legislative appropriation devoted to the Agricultural Department, the Consular Service, the District expenditures, etc., we have been obliged to omit in our reproduction.

It will be remembered that under the continuing contract system now in force, the River and Harbor appropriation represents, perhaps, a half of the present expenditure for works of this class. Even with this increase, however, it will be seen that the money spent on public works is less than half the amount required to carry on the various departments of the government, which are covered by the term "Legislative." The next division to the right represents the amount spent for national defence, which will be seen to constitute nearly a fifth of the total national expenditures. Pensions, however, are responsible for the great bulk of the increase in our national expenditures during the past decade, having risen from $20,000,000 to a present annual payment of $150,000,000 in that time. It seems practically certain that this item of expenditure will rapidly decrease from now onward, though, with the chances of future pension legislation and the possibilities of superannuation pensions being established in the civil service, it is doubtful whether the pension bill will be reduced to the figures of 1885 for many years to come, if at all.

RECORD OF STEAM SHOVEL WORK; ANN ARBOR R. R.

In a paper on "Improvement Work on the Ann Arbor R. R.," *presented at the meeting of the Michigan Engineering Society, in 1895, Mr. H. E. Riggs described the improvement work which has been carried out by that railway, and the most generally interesting part of the paper was the record of work done by steam shovels in cutting down the grades. This work has been done by the company direct, using steam shovels of various makes, all having dippers of 1½ cu. yds. capacity, while the material was plowed off the cars by a Barnhart center unloader hauled by the engine of the work train. The following is an extract from the paper, and the discussion thereon. The first part of the table is the record of work done in 1894, by the Toledo, Ann Arbor & North Michigan Ry., while the second part is the record of work done during the season of 1895, when the road was reorganized as the Ann Arbor R. R.:

The past season has been one of great activity, six shovels being at work, and for a greater part of the time we have worked both day and night shifts. This fact has rather impaired the value of our statistics, as all of our measurements are based on actual pit cross sections, and it was absolutely impossible to separate day and night work. In making up the statement, a night's work is counted as a day, thus affecting the average hourly output of the shovel. Another feature of uncertainty is the fact that the number of locomotives in attendance on the shovels varied from time to time, and the record of such movements was difficult to keep. The additional fact that no form of report was used, all data being compiled from daily telegraphic reports, made it impossible to secure as complete a record as was desired.

With this general outline I would submit the table of cost. All figures represent cost of earth under the track, including all labor of shovel crew, train crew and trackmen, fuel and supplies, but do not include any figures for rental of plant, repairs, or any charges for service of telegraph, station or other employees; nor do they include engineering or superintendence (other than foreman).

It is to be regretted that there is not more literature on steam shovel work, the work of Mr. E. A. Herrmann, in Engineering News, some two years ago, being the most complete discussion I have seen. (This is now published in book form.—Ed.) Records of cost of such work, however, are rare, and these are the most valuable information that can be had, for any one about to begin work of this nature. The steam shovel and its relation to railway reconstruction has been but little discussed, but this machine has a great future of usefulness in the work of railways, as will be seen by the work done on the Ann Arbor R. R.

The average cost for moving the material for the entire time will be about 14 cts. per cu. yd. The average haul was 2½ to 3 miles. On one piece of work we hauled as high as 20 miles, and very little was hauled less than half a mile. The average haul would be fully three miles. The cost of the work would have been much reduced if we had had the advantage of a double-track railway, instead of working on a single track. It is hard to say what per cent., but the greater portion of our delays were caused by the interference of regular trains on the road. On the south end of the road, particularly south of Dundee, where we have the trains of our own road and those of the Cincinnati, Jackson & Mackinaw Ry., we have had about 50 trains per day and the delay was considerable. We had one or two instances in the district where we did not average over 3½ hours work out of a ten-hour day.

---

LEGAL DECISIONS OF INTEREST TO ENGINEERS.

Right to Trim Overhanging Trees.

A traction company authorized by the city to erect its trolleys has the right to top the branches of trees overhanging the street when such act is reasonably necessary for the passage of its wires.—Dodd v. Consol. Traction Co. (Supr. Ct. of N. J.) 31 At. Rep. 980.

Liability of Municipal Officers.

Municipal officers will not, in the absence of malice or culpable negligence, be personally liable for damages caused by constructing a sewer across private premises under the authority of the city.—Parks v. City Council of Greenville. (Supr. Ct. of So. Car.) 21 S. E. Rep. 540.

Contract for Street Lighting.

A city, before the expiration of its contract with a gaslight company for street lighting, discarded the use of gas, and adopted electric light. The gas company continued to light its street lamps and sued for the gas so consumed. Held that it could not recover, its remedy being only for the breach of the contract.—City of Newport v. Newport Light Co. (Ct. of App. of Ky.) 30 S. W. Rep. 606.

Damages Not Limited to Bill Presented.

Where a party having sustained a personal injury for which he claims that a city is liable, presents his bill to the city council for allowance, and is by it disallowed, he may sue for and recover all damages sustained, though such damages exceeded the amount claimed in the bill, and on such judgment recover also costs.—Oklahoma City v. Walsh (Supr. Ct. Ok.) 41 Pac. Rep. 598.

Removal of Snow by Street Railways.

A city ordinance providing that when snow falls of a sufficient depth for sleighing, no snow plow shall be allowed on the tracks of a street car company, and that it shall not remove snow from its track without the consent of the superintendent of streets or mayor, does not prohibit the use of snow plows when the consent of the proper officer has been obtained.—Ovington v. Lowell & S. St. Ry. Co. (Supr. Jud. Ct. of Mass.) 40 N. E. Rep. 767.

What Must Be Shown to Recover Damages.

Where the evidence shows that one's premises abutting on an elevated railway had increased in value since the road was built, he cannot recover for damages to such premises caused by construction and operation of the road, unless he shows that there has been a general advance in the value of property in the neighborhood, not attributable to the road, of which he was deprived by the construction of the road.—Beck v. Brooklyn El. R. Co. (Supr. Ct., Gen. Term, 2d Dept.) 33 N. Y. Sup. Rep. 764.

Liability of City for Failure of Duty by Board of Health.

The duty of keeping the streets clear of putrid and other substance offensive to the sense of smell, and which tends to imperil the public health, devolves, under the charter of the city of Atlanta, upon the board of health of that city; and the functions of this department of the city government being governmental, and not purely administrative in their character, it follows that if, in the exercise of such functions, and in the discharge of the duties devolving upon this department, a private citizen is injured by the negligence of one of its servants in and about such work, no right of action arises against the city. In order to exempt a city from liability, it is not sufficient to show that the particular work from the negligent performance of which by the servants of the city a citizen was injured was being performed under the direction of the health authorities, but it must be shown that the particular work so being done was connected with or had reference to the preservation of the public health. If the health department were engaged in clearing away or removing obstructions from the street which in no way endangered the public health, the responsibility of the city then would rest upon the rule of liability for the work connected with repairing and keeping in order the public highways. It can make no difference in principle as to the character of the agents employed in the discharge of this duty with respect to the public health. The principle of non-liability rests upon the broad ground that in the discharge of its purely governmental functions, a corporate body to which has been delegated a portion of the sovereign power is not liable for torts committed in the discharge of such duties and in the execution of such powers. It can be no more liable because of the fault to select competent drivers of garbage carts than a city could be held liable for failing to elect a wise, conservative and discreet mayor.—Love v. City of Atlanta. (Supr. Ct. of Ga.) 22 S. E. Rep. 29.

BURNSIDE SHOPS, ILLINOIS CENTRAL R. R.

(With inset.)

III.

Car Shops.

In the two preceding articles describing this railway shop plant the track and ground constructions, minor buildings, buildings common to both locomotive and car work and the locomotive shops have been described and illustrated. In this article the car shops and heating system are described.

The car shops at the Burnside plant comprise six buildings as follows: Mill Building, Passenger Car Repair Shop, Freight Car Repair Shop, Passenger Car Paint Shop, Dry Kiln, and Dry Lumber Storage House. All of these buildings are grouped at the north side of the plant, and each will be described in such detail as its structural features seem to warrant.

Mill Building.—The mill building is 362 ft. 2 ins. long and 160 ft. wide, with a 45 × 100 ft. annex on the east side for the power plant, which runs the various wood working machines. Fig. 18 shows a transverse and a part longitudinal section, which give the roof trusses and other iron work in outline. A row of columns, 40 ft. apart, extends the length of the building at the center and carries a longitudinal truss. The roof trusses are spaced 20 ft. apart and connect at the center alternately with the columns and with the longitudinal truss. Fig. 19 shows the details of both styles and connections, and the column construction. At the outer ends the roof trusses rest on the walls to which they are anchor-bolted through oblong holes to allow of motion due to expansion. The purlins are 8 × 12 ins. × 22 ft. timbers, placed at panel points, and the jack rafters are 2 × 6 ins. timbers spaced 2 ft. c. to c. and covered with 6 × 1⅛ in. matched sheeting covered with "Actinolite" composition roofing. Fig. 20 shows the construction of the longitudinal truss and also the longitudinal ridge truss of the skylight frame. Other details of the skylight framing are shown by Fig. 21. The trussed purlins indicated by Fig. 18 in outline are of the same character of construction as the longitudinal center truss.

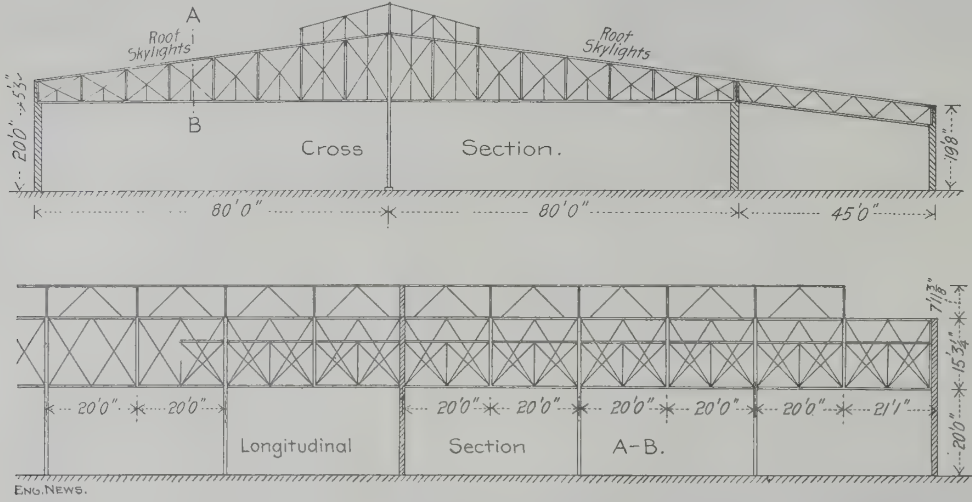

FIG. 18.—TRANSVERSE AND PART LONGITUDINAL SECTIONS OF MILL BUILDING SHOWING FORM OF FRAMING.

Besides the lantern or ridge skylight there is a row of smaller roof skylights on each side and occupying the space between panels three and four of the roof trusses, as shown by Fig. 18. The design and construction of one of these roof skylights are shown by Fig. 22. This drawing gives the construction in such detail that further description of that feature is unnecessary. This form of skylight was adopted on account of the flatness of the roof which made the ordinary form of flat skylight undesirable. Experiments showed that a slope of 1 in 4 at least was necessary to prevent the gathering and dripping of condensed moisture on the under side of the glass, and these skylights were designed to avoid such trouble.

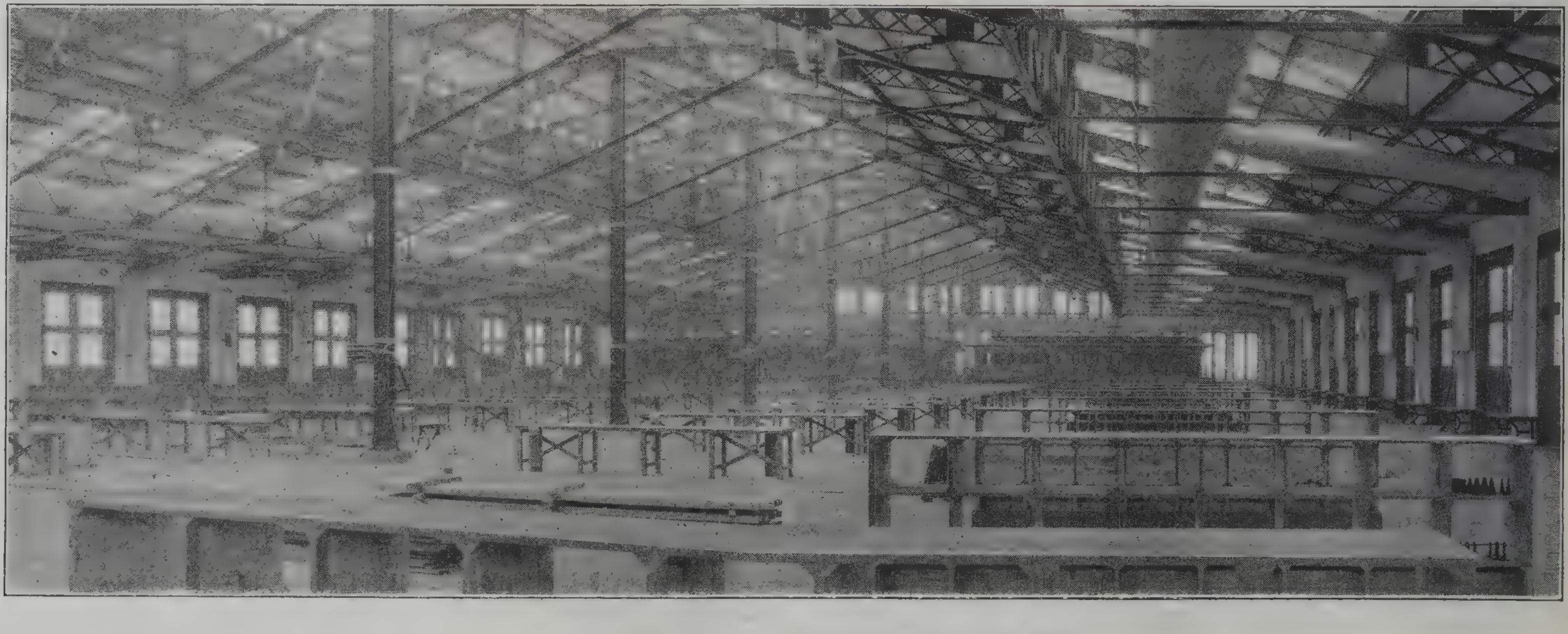

FIG. 24.—INTERIOR VIEW OF PASSENGER CAR REPAIR SHOP.

The interior arrangement of the building is simple. At a distance of 120 ft. from the south end, the building is divided by a transverse brick firewall, having double doors of ⅛-in. sheet iron. This portion of the building is divided by wooden partitions into a truck shop, 120 × 60 ft., a cabinet shop, 120 × 60 ft., and an upholstering shop, 120 × 40 ft. North of the fire wall the building is devoted to general wood working machinery. In the annex or engine house are a 400-HP. Sioux City Corliss engine for running the machinery, and a 20 × 30 ins. duplex Rand air compressor, capable of furnishing 1,800 cu. ft. of free air per minute compressed to 150 lbs. pressure with 80 lbs. steam pressure. This air is piped to all parts of the shops and grounds for various purposes. The heating apparatus for the building is also located in the engine house.

It may be noted before leaving the description of this building that the location and arrangement of the tracks entering it and all the other buildings as well, were shown on the general plan of the whole shop plant, published in our issue of June 18. Details of the track and floor construction for the mill building, however, are shown by Fig. 24, this floor being the same in its general features as that for the passenger car repair shop described further on.

It is almost unnecessary to say that this building is used for preparing all timber used in the car repairs, it being sawed, planed and otherwise worked into shape here. Push car tracks connect it with the dry kiln and dry lumber storage house which are described further on.

Passenger Car Repair Shop.—This building is the same size as the mill building, 362 ft. 2 ins. × 160 ft., and, as in the mill building, a center row of columns carries a longitudinal truss, which, together with the columns, support the roof trusses at the center. The columns are spaced 40 ft. apart and the roof trusses 20 ft. apart. Fig. 23 shows the general design of the roof trusses, longitudinal trusses and longitudinal trussed purlins, and the interior view, Fig. 23, will aid to an understanding of the general arrangement and construction of the same parts.

The top chords of the roof trusses have a triangular lateral bracing and carry Z-bar purlins upon which are the wooden jack rafters, sheeting, and "Actinolite" composition roofing as in the mill building. The building also has the ridge lantern and side skylights, but the latter instead of being raised as in the mill building are flat. Altogether 2-7 of the roof area is glass and as a consequence the interior of the building is very light, as will be seen from Fig. 24.

The interior of this building is not subdivided, it being devoted entirely to one use, namely, passenger car repairs. A series of 18 parallel tracks with a capacity of 36 cars at one time cross the building transversely and onto these the cars are run for repair. Fig. 25 shows the track and floor construction. Between each pair of tracks the floor space is given up to racks and benches and to the use of the workmen, as shown by Fig. 24. This view also shows the piping for the heating system, the system of side doors, and minor details of construction and equipment.

These side doors are deserving of further mention, and in Fig. 26 are shown one type of double door and a push car door. The doors of the second type are of the same dimensions, but the construction is different, they being divided transversely about midway up, so that the bottom half can be opened independent of the top half. Owing to this construction the suspension rods extend from the top outside corners to the bottom inside corners of the upper doors only. The bottom windows also, instead of being the same size as the top windows, 4 ft 6½ ins. × 4 ft. 6½ ins., are only 2 ft. 5½ ins. × 4 ft. 6½ ins. There is also no wicket door in the main doors. Altogether there are 21 doors of this type, 14 of which are in the mill building.

Passenger Car Paint Shop.—This building is located just east of the passenger car repair shop, and is of the same size. A transfer table between the two buildings provides for the easy transfer of cars from one to the other. The framework of the building is also very similar in all respects to that of the passenger car repair shop. About one-half of the roof area is glass, making it very light.

At the north end of the shop there are three small rooms, devoted, respectively, to cleaning brass work and car fittings; to the storage and mixing of paints, and to the storage and preparation of varnish. The main portion is crossed transversely by 17 parallel tracks, on which the cars are stored for painting. The track and floor construction are shown by Fig. 27. Owing to the

large amount of water used in washing and the drippings from the cars this floor is of concrete and so troughed that drainage is rapid to the sewer pipes underneath it. These sewer pipes run lengthwise of the building, one near each side and one at the center. On the lines of these pipes there are open gratings and connecting pipes between the rails of each track, and also at the center of the floor spaces between tracks. Midway between the side and center lines of pipe the floor is crowned.

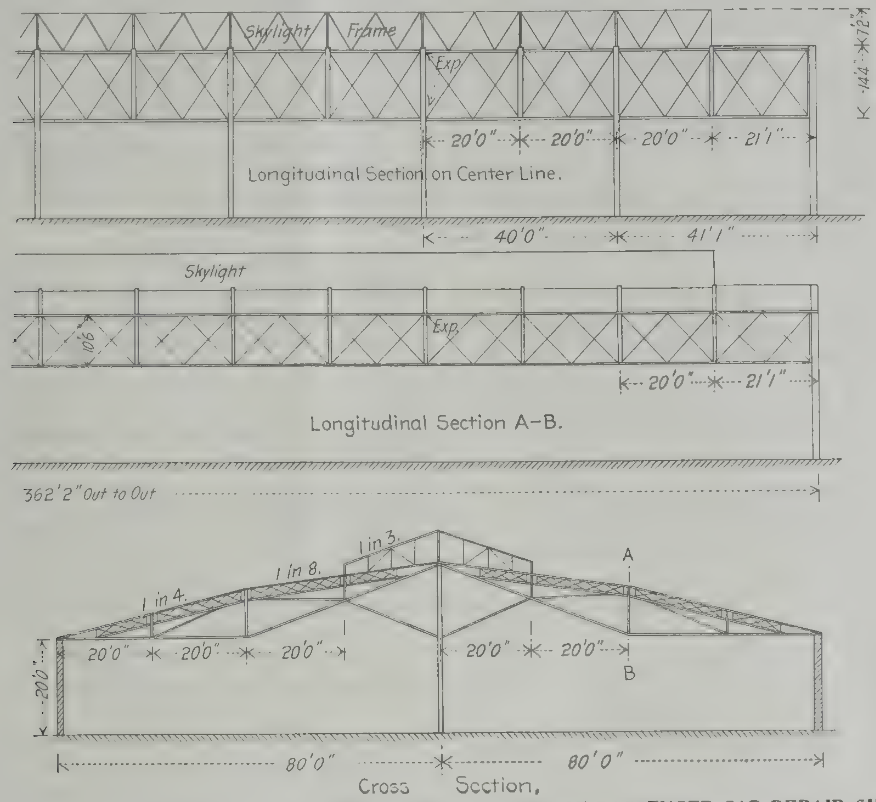

FIG. 23.—TRANSVERSE AND PART LONGITUDINAL SECTION OF PASSENGER CAR REPAIR SHOP.

Freight Car Repair Shop.—This building is 502 ft. 2 ins. long and 100 ft. wide, and the roof trusses span it from wall to wall without intermediate columns, as is shown by the interior view Fig. 28. The ridge lantern is the same as for the other buildings described, and the roof skylights are of the raised trapezoidal type already described for the mill building. Four tracks run lengthwise of the building which is not subdivided. Fig. 30 shows the track and floor construction.

The tracks in the building have a capacity of 44 35-ft. cars at once, and here all of the heavy repair work will be done. The yard tracks at the west end of the building will also be used for cars needing light repairs. Both this shop and the passenger car repair shop are thoroughly fitted with pipes for compressed air, which will be used to operate jacks, hoists, and such other power appartus as may be used.

Dry Kiln.—This building calls for attention chiefly on account of the system of drying used. At one side of the building is a small annex in which are located a Sturtevant heater and fan of the construction described farther on under the head of Heating System. From this heater a large supply pipe passes transversely across the building underneath the floor near one end. Right angle branch pipes, six in number, convey the hot air from the main pipe and discharge it through the eighteen 15-in. openings in the floor. At the opposite end of the building the hot air is exhausted into ducts which lead it back to the heater again, or it is sent to the outside—if rapid drying is desired. The lumber is run into the building on special tracks, and then subjected to the circulating hot air until seasoned. It will be seen that the system described is the well-known "Sturtevant Patent Progressive Lumber Dry Kiln," of the B. F. Sturtevant Co., of Boston, Mass.

Dressed Lumber Storage House.—This building calls for no extended description. It is used to store seasoned and dressed lumber and is 100 ft. long and 75 ft. wide.

Steelwork.—The general design of the steel framework for the different car shops has been described. Two classes of material were called for by the specifications, soft steel for rivets and medium steel for all other parts. All steel was required to be made by the open hearth or Bessemer process, and to contain not more than 0.1 of 1% of phosphorus or 0.6 of 1% of sulphur. In tests of ¾-in. diameter bars it was to show the following results:

	Ult. strength, lbs. per sq. in. Max.	Ult. strength, lbs. per sq. in. Min.	Min. elastic limit, lbs. per sq. in.	Per cent. Elong.	Per cent. Reduc.
Medium steel	66,000	58,000	38,000	20	44
Soft steel	58,000	50,000	30,000	28	50

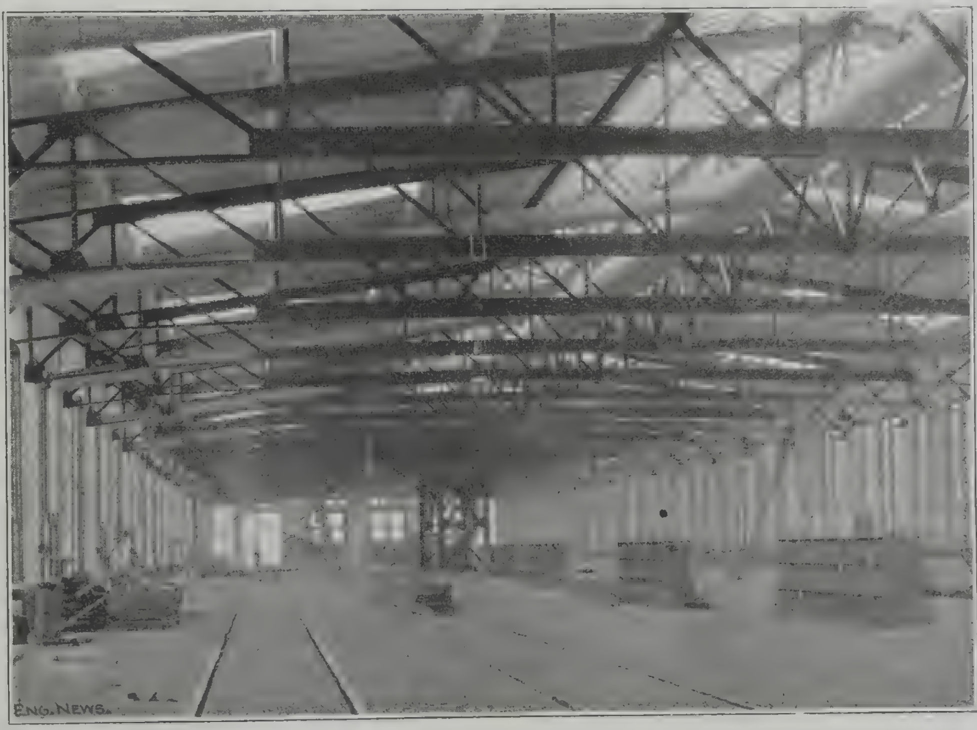

FIG. 28.—INTERIOR VIEW OF FREIGHT CAR REPAIR SHOP.

The usual bending and drifting tests and a chemical analysis were also required. All material was inspected before shipment. Before leaving the mill all material was cleaned and given a coat of raw linseed oil, and after erection it was given two coats of paint.

The steel was furnished by Carnegie and manufactured by the American Bridge Works, of Chicago, Ill.

Heating System.—The immense areas of these shops introduce a problem in heating which could be solved only by a very extensive and efficient plant. After full consideration it was decided to adopt the B. F. Sturtevant Co.'s hot blast system, the essential features of which is well-known consist of the steam coils, the air duct leading all over the building to be heated and the blower or fan for forcing the hot air through the duct. The advantage claimed for this system is that the air is kept in motion and does not become robbed of its heat by coming into contact with cold walls, and other large exposed surfaces. The hot air is discharged near the floor, and in ascending is claimed to give an even temperature.

The details of the heating system differ somewhat in each building, but the general design is the same for all. Referring to Fig. 23, showing the interior of the passenger car repair shop, it will be seen that two large air pipes pass lengthwise of the building, one on each side of the roof. These two pipes are carried by the roof trusses, and from them at intervals pipes extend at right angles along the roof slope to the side walls and then bend down by means of an elbow. Hot air from the two main pipes is thus discharged near the floor at the side walls.

The heating apparatus proper consists of a rectangular system of steam coils inclosed in a box, one end of which is open for the entrance of air, and at the other end of which is placed the fan or blower. This blower is operated by an independent engine which exhausts into the steam coil and supplies the heat necessary to warm the air. The operation is obvious. Air is sucked into the box between the steam coils and then forced into the system of supply pipes. In the paint shop the air is taken from the outside to secure the best possible conditions for drying paint, but in the other buildings it is taken from within and thus is simply circulated about therein. In the freight car repair shop the fan is 20 ft. 5 ins. high and 5 ft. wide, and is run by a 8 × 20 ins. engine. The coil has 12,000 ft. of 1-in. pipe. In the other three car shops the fans are 20 ft. 5 ins. high and 6 ft. wide, and are run by 11½ × 16 ins. engines. The heating coils each have 14,500 ft. of 1-in. pipe. In a previous paragraph the heating plant for the dry kiln has been described.

In the foregoing paragraphs, and in the two articles preceding the various structural features of the great shop plant of the Illinois Central R. R., at Burnside, Ill., have been described. The study of the drawings presented furnish many suggestions for thought which have not been mentioned, however, and in our editorial columns some of these have been considered.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32*d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The deficient force of the city engineering departments of many of our cities is brought to mind by some comments in the "Call," of Newark, N. J., regarding the size of the engineering corps in that city. Recent severe storms in Newark have greatly overtaxed the facilities for the removal of surface drainage. The "Call" states that the lack of proper drainage facilities has caused much loss to individual property owners and the city as a whole, and discusses the demand for larger storm sewers, the overhauling of gutters, and the protection of walks and cellars. In speaking of the work that should be done it calls attention to the need of a larger engineering staff as follows:

> The real obstacle to this is in the engineering department. There are excellent workers in this branch of the city government, but it is absurdly inadequate in the number of men and in the amount spent for engineering purposes. The city is, for instance, required at the present time to maintain a constant engineering supervision over the water-works, both as regards the old construction and the new. This will continue after the city has acquired full control, and is likely to grow greater. It now takes most of the time of the chief engineer and one assistant. For the rest of the force there is the sewerage system, the paving, the grading and opening of streets and a thousand and one details. How the two or three men available now manage to get through with the work it is hard to guess. That they could do more, yet do it thoroughly, no one believes. The city has never been willing to spend enough money in this line, and it is proving an expensive economy. More liberal ideas should control, and with the enormous amount of work under way or impending, the subject can not be considered too soon.

When a daily paper urges an increase in the engineering force of a city it may be pretty generally assumed that such an increase is needed, but it is only fair to say that this particular paper discusses public improvements with unusual discernment.

We shall not venture to discuss the needs of Newark, but the representations made by the "Call" are entirely in accord with the conditions in many other localities. Happily there are a growing number of instances where the economy of employing a sufficient number of competent engineers is recognized, and where it is also perceived that the only way to get and keep good men is to pay them ample salaries. Where large sums are being paid out yearly for public improvements a thoroughly competent engineer will save a city daily the difference between the yearly cost of his services and those of an incompetent man. Where not enough engineers, even of an indifferent character, are employed, the saving might be even more marked if such folly were abandoned and the right course pursued.

Vast improvements are being made in methods of carrying out all classes of public works. The municipality that does not employ engineers thoroughly abreast of the times is continually liable to adopt discredited methods. These will lead to heavy yearly charges for a time, and then have to be abandoned, where the proper course would have meant light annual cost for maintenance and long years of useful service. In engineering, if anywhere, "the best is none too good." There is here, as elsewhere, a limit to what one man can do and do well.

Possible further economies in railway operation and in railway service are the subject of a good deal of discussion at the present time, when competition and bad financial conditions are combining to reduce railway earnings, and such conditions are a spur to good managers to devise new methods by which they may legitimately reduce expenses and work the equipment more economically without reducing the efficiency of the service. The Erie R. R. has recently introduced two somewhat notable improvements in operation which may be expected to produce a decided economy. In the first place it has adopted the system of rating freight trains on a tonnage basis, instead of by the number of cars. This system has been very much discussed of late and the discussion has shown that under the ordinary practice there is no uniformity in the train loads, since a large proportion of the cars contain but a very small percentage of their freight carrying capacity, so that an engine hauling its full complement of cars may be loaded far below its economical capacity, while the dead load of the train is out of all proportion to the paying load which it carries. Under the new system the cars are, as far as is consistent with prompt and efficient service, loaded to the proper capacity, and the weight of the freight in each car is made out on the way bills, so that the men in charge of making up the trains can readily see how many cars may be attached to a certain class of engine. This system is found to work very well and very smoothly, even with connecting roads, and it not only tends towards economy in general operation, but also enables the locomotives to be worked under conditions more favorable to economy and efficiency of the motive power equipment.

The second improvement above noted is directly in connection with the economical operation of the motive power equipment, and consists in doubling the run of the passenger engines from Jersey City. Formerly one engine hauled a through train from Jersey City to Port Jervis, 88 miles, and then another engine took the train on from Port Jervis to Susquehanna, 104 miles. Now, however, one engine makes the through run of 192 miles, and it is easy to see that a considerable economy in fuel consumption may be expected, since the longer the engine is kept in regular service on the road (that is to say, the longer its straight run) the less will be the amount of fuel lost in banking and rekindling the fires. If an engine makes a run of 88 miles and then goes into the yard or round-house to wait for some hours before going on the road again, it will manifestly be handled to less advantage as a machine than if it makes a run of 192 miles before laying up. As to the question of repairs, there seems to be no reason why these should be increased; in fact the boiler is likely to be less severely strained if worked uniformly for a greater period of time between the banking of the fire. A few years ago, when the Strong locomotive, with double corrugated flue furnaces, was being tried on different roads, one of the claims made for it was that the use of two independent fires enabled the fires to be kept bright and the grates clean for a much longer run than was practicable with the ordinary locomotive having but a single fire. This engine, on one occasion, made the through run of over 400 miles, from New York to Buffalo, over the Erie R. R., hauling the regular day express, and returning with the eastbound express on the next day. The number of men required to feed the fires, to tend the doors, and to pass the coal down to keep a supply on the tender deck, made the run of little moment from an economical point of view, the experiment being mainly with a view to showing the practicability of increasing the direct run of locomotives. If an ordinary engine with its regular crew can successfully make a run of 192 miles instead of 88 miles, it probably means that another element in economical operation has been introduced. It is not improbable that the runs of freight engines on the Erie R. R. may be increased in the same way.

We are informed that the bridge which fell under an electric car of the Dayton Traction Co., on July 1, as noted in our issue of July 9, was not a wooden structure but a new steel bridge. What the merits or demerits of the structure may have been, we do not know; but it is evident that a steel truss is not proof against the impact of a derailed car, and that this accident ought not to be passed over merely as another case of a weak and flimsy bridge falling under a load. The lesson which these and other recent accidents ought to carry to engineers is that proper guard rail protection should be provided on all through-bridge spans crossed by electric railways to prevent a derailed car from running into and wrecking the trusses.

THE ARRANGEMENT AND CONSTRUCTION OF RAILWAY SHOP PLANTS.

Division of labor is to-day recognized as an essential characteristic of manufacturing. It has been found that in no other way can production be made so rapid and so economical in material and labor. To produce a manufactured article a number of processes are required, each different from the other, in the appliances used, and the character of skill required of its working force, but all co-operating to the same end—the production of a single, complete, marketable article. In designing a manufacturing plant, then, it follows that this differentiation of appliances and manual skill must be recognized if the best use is to be made of the mechanical power and the cunning of workmanship, of its equipment of machines and men. The railway shop plant is a kind of manufacturing plant, and the same principles which apply to the successful operation of other manufacturing plants apply to its operation.

On another page we conclude the description of the shop plant of the Illinois Central R. R., at Burnside, Ill., one of the largest and most modern plants of the kind in this country. In view of these facts it has seemed profitable to consider briefly some of the salient features of good construction and arrangement which that plant seems to exemplify, and to draw from them such lessons as may be profitable in the light of the conditions usually governing the construction of such plants.

Perhaps the first question which comes up in the construction of a railway shop plant is its location. We have already discussed this question at length in relation to general manufacturing plants, in our issue of April 9, but the conditions with railway shop plants are somewhat different. Their products are not for the general market. Like the repair shops of a manufacturing establishment, railway shops are merely an accessory to the various processes necessary to produce the marketable material, which is for railways safe and rapid transportation of passengers and freight. The location of the plant, then, has to be considered only in respect to the question as to how it will best subserve the demands of the railway to which it is an adjunct. Only in so far as that location affects its ability to produce marketable transportation is the railway company concerned with the industrial and market conditions of the country in general in selecting the location for its shops.

How to subserve best his own particular conditions is then the thing which the railway manager has to consider. The factors which enter into this problem are many, but we think they may be gathered under the following heads: (1)

Convenience of location in respect to the accommodation of the system as a whole; (2) Convenience of location in respect to the centers of supply of material and labor; (3) Advantages of location in respect to cost of land and buildings, facilities for extension, taxes, etc.

The relative importance to be given to each of the above considerations will evidently be different for almost every railway. If traffic were equally dense and important on every part of the system, a central location of the shop plant would theoretically, accommodate best the system as a whole. But traffic is not equally dense and important on all parts of hardly any railway system. Moreover a central location may be very inconvenient to the centers of supply of labor and material. Again, in the infancy of the system the headquarters of the officials and the earlier shops may have been located at a point far from the center of the system as it now exists. These considerations may be important enough to determine the location of the general shops at the extreme end of the system, even to the extent of compelling a greater expenditure in establishing division shops.

The consideration of the advantages of location with respect to cost of land and buildings, facilities for enlargement, etc., needs to be kept separate from the others, for there are certain factors in the construction of railway shops which remain constant irrespective of location as determined by other conditions. Perhaps the most important of these is space. Great space is a necessity in railway shop plants: (1) because the things to be handled—cars and locomotives—are of large size, and (2) because their weight and size prohibit the use of multiple storied buildings. Single story buildings are a practical necessity, and increase of floor space in them means absolutely an increase in their ground area. The bearing of this condition upon location is obvious. The shop plant must be situated where land is cheap and taxes low. This means, aside from exceptional cases, that the location must be outside of our larger cities. There may be cases, of course, where the railway company has ample space for shops within a large city, space secured when the city was young and land cheap, but this is not often the case. The area of high priced city land available to most railways is too valuable for freight yards and terminals to be given up to shop plants which can just as well and perhaps better be located elsewhere.

A case in illustration of this is the Illinois Central Ry., whose new shop plant we have been describing. This company holds property within the city of Chicago, the extent and value of which is exceeded by the city land held by few other railways. Until 1892, a part of this land had been occupied by car and locomotive shops, but increased traffic demanded larger terminals, and larger terminals required the use of the land occupied by the shops. The result was that the shops were removed outside of the city a dozen miles. The gain was a better location for the shops and the freedom of the land once occupied by them for more valuable purposes.

Let us consider this location in the light of some of the other considerations which have been mentioned above. Chicago is at the extreme limits of the Illinois Central Ry. system—at the extreme north of its southern line and at the extreme east of its westward line. General shops at Chicago were equally available to both lines. This city was, moreover, the headquarters of the official force of the road, it is a great center of supply for coal, lumber and iron, and the home of numerous men skilled in mechanical pursuits.

This consideration of questions affecting the location of railway shop plants might be prolonged, but it is our purpose here to discuss more particularly the principles governing the arrangement and construction of such a plant after the location has been decided upon. The best arrangement and construction to be adopted in a particular plant depends, of course, upon the character of the work it has to do, but a certain broad principle governs the arrangement and construction of all plants, and it is the concentration and grouping of buildings and equipment to secure a systematic and efficient division of labor. In a general repair shop for a railway there are two classes of work widely different in many respects, but at the same time having many points of similarity, viz.: the repair of locomotives and the repair of cars. There are also certain processes and kinds of work equally common to both classes. It is known that in locomotive work there are several processes, viz.: blacksmithing, boiler making, machine work, erecting, and several minor processes. Likewise in car work there are blacksmith work, wood work, carpentry, erecting, painting and minor processes. It is evident that the similarity between any two processes of locomotive work is generally closer than between the processes peculiar to locomotive work and those peculiar to car work. Further, it is evident that the different processes of boiler work are more closely related than the processes of boiler work and machine work in their entirety. Applying the broad principle stated above, the first point to be considered then is the differentiation of the various structures of the plant to suit the conditions of the various processes. The first broad differentiation is the grouping of the buildings, the second is the selection of the proportionate space and arrangement of the buildings in each group, and the third the interior arrangement of each individual building to suit the work to be done in it. Equally important with the above is the arrangement of the track system to furnish short and easy transport from one building to another, and an adequate provision for future extensions of the plant.

It is not the purpose here to discuss in detail the best method of grouping, and sub-grouping railway shop plants, because the conditions will require different forms in nearly every case. What it is wished to emphasize is the desirability of careful attention to this feature. The Illinois Central Ry. shops furnish a good example of this attention to the division of labor and grouping of buildings and are deserving of study for that reason. The points to be noted particularly are: (1) The separate grouping of the car shops and locomotive shops, with the buildings common to both between them and equally available to either; (2) in each group the location of the buildings between which communication is most frequent nearest to each other, and the provision of special facilities for transport; (3) the adoption of systematic provisions for transportation, sewerage, water supply, fire protection, lighting, etc., so as to concentrate the power machinery and collateral apparatus and to economize in the labor force required for their operation.

Turning to the individual buildings for railway shop plants, there are several requirements to be considered in their construction. Such construction must be chosen as to develop and utilize the best abilities of the workmen as well as of the machinery. The requirements to this end are ample floor area, the avoidance of unproductive travel and of floor spaces not open to immediate observation, abundant and uniform lighting, efficient heating and good ventilation and sanitation. As railway shops must of necessity be single story buildings, ample floor area is to be secured only by buildings of great lateral dimensions. This gives the best possible conditions for abundant and uniform lighting and good drainange and ventilation, but not so good conditions for easy heating nor for overlooking the workmen and avoiding unproductive travel.

By the liberal use of skylights a single story shop can be made almost as light as outdoors and there is little limitation to the use of such lights up to half the area of the roofs with the use of wire glass and the proper construction of the skylight frames. By making a portion of these lights movable, ample ventilation is secured. The questions of drainage and sanitation are also simplified. With the proper gratings, catch basins and crowning, the floors can be flushed clean with a hose and all drippings of grease and water adequately disposed of.

The difficulty of easy heating makes it a feature to be looked after only the more carefully. It is too often the case that the difficulty is met in railway shops by burning more coal rather than by installing an efficient heating system. Not many months ago in a discussion before a prominent railway club a well known superintendent of motive power made the statement that he did not think there was a shop on his system which was economically heated. Crude appliances installed and added to in a haphazard manner were the cause. Many other roads are suffering in the same manner. In the thoroughness of their heating system the Burnside shops of the Illinois Central R. R. stand as a monument of good sense and good engineering among railway shop plants in this country, as well as in their lighting, their drainage, and their other appliances for providing for the sanitary needs of the working force.

These points are mentioned here not alone because of their humanitarian desirability but because experience has shown that they mean a gain in dollars and cents by furnishing the best conditions for effective and rapid work. Take an illustration: it may seem of little moment whether the floors of the pits in a round house are crowned or dished as far as efficient drainage alone is concerned, but a man works dry shod in one and slops around and wastes time in keeping out of the water in the other. So it is often with other details of construction, but further than this, the effect of a clean, well lighted, well ventilated, well sewered and generally comfortable shop on the health, habits and disposition of the workmen can but be wholesome. This is a thing which has been learned by our most progressive manufacturers, many of whom go to almost excessive lengths in this direction, but a too small number of railway managers give it their attention, if we may judge from their shops.

Another important feature of shop construction is the interior arrangement. The best modern practice inclines toward single floor shops with as few dividing walls and partitions as possible. The reason for this is threefold, the lighting is better, unproductive travel is reduced, and the workmen are directly under the eye of the foreman from every part of the building. Probably the maximum division allowable is the separation of distinctly different departments, and when on the same floor and unless for good reason privacy is necessary it is an open question whether separating partitions are advisable even to this extent. The machine shop of the Burnside plant is open from one end of the building to the other. Even the office of the superintendent and foreman is a polygonal cabin with windows on all sides so that it affords a conning tower from which all points of the shop are visible. In railway shops the convenient obscurities of cars and locomotives are frequent enough temptations to loitering workmen without taking trouble to provide them in the shape of partitions, even if such construction was not objectionable for other reasons. It may seem to some that disproportionate stress is laid upon the interior arrangement of the shop in its relation to securing the best abilities of the men, but we believe that the experience of the best shop construction and practice will testify to the importance of this feature. The output of a shop is directly dependent upon the alertness, vigor and attention to duty of the workmen, and anything that acts to keep these faculties at the highest point acts to increase production.

Little has been said thus far about the purely structural features of the building construction in railway shop plants. Generally these are simple. The large area of roof and the provision for shafting, traveling crane tracks, and supports for hoists and suspended machinery are about the only things which introduce complexity. In the ordinary railway shop building the roof trussing is simplified and lightened by the frequent use of interior columns, which are also necessary for the support of the crane tracks and overhead machinery. Heavy hoisting and conveying machinery in the shape of bridge cranes, air and steam hoists, etc.,is almost a necessary requisite of the locomotive shops and adequate provision should be made for them in constructing the framework, even though their use may be a thing of the future. At no other time will the task be so easy and inexpensive as during the first construction.

Architectural embellishment is a feature for minor consideration, although effort should always be directed to secure a neat and substantial appearance of the buildings. Uniformity in the spacing and construction of doors and windows and the lines of the brick walls does a great deal in this direction, and is moreover a measure of economy in construction.

It is recognized that little has been said in the foregoing which is not already known, but young engineers are constantly coming up who are not familiar with all these considerations and sometimes older men appear by their work to have forgotten them. It does not seem time and space idly spent, therefore, to emphasize the principles of railway shop construction in connection with the practical example of such work to which we have given so much space.

LETTERS TO THE EDITOR.

Proposed Standard Specification for Portland Cement.—Correction.

Sir: Referring to my article published in your issue of July 16, I would like to correct one error on the last column of p. 35, where it says: "Quick setting, final set to be not less than 30 minutes." It should read, "Quick setting, final set to be not over 30 minutes." This was a typographical error in the pamphlet which I got up, and which I did not notice until my attention was called to it a few days ago. There are no other errors in the article.

Yours very truly,
Wm. J. Donaldson.

Betz Building, Philadelphia, Pa., July 21, 1896.

A Confusion in Titles.

Sir: The following incident is brought to mind by the recent meeting of the Christian Endeavor Society at Washington: A member of the engineering corps of a prominent steel manufacturing concern, desiring to purchase a certain book on the subject of his profession, had his office boy go the rounds of all the leading book stores of the city for the purpose of procuring a copy, but without success, until finally the youth brought up at the United Presbyterian Book Store. Upon afterwards being asked what reason he had for inquiring at a store in which technical books are not ordinarily kept in stock, he replied that he thought they must have it for he saw a sign in the window which read, "C. E. Supplies."

J. C.

Pittsburg, Pa., July 17, 1896.

Dangerous Reference Points.—A Warning.

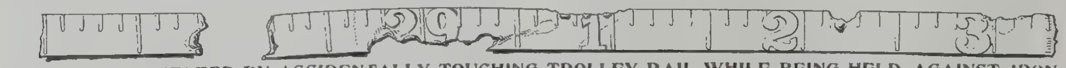
Sir: The enclosed pieces of steel tape were melted to-day by an electric current. In referencing a street monument from an iron trolley pole, the tape touched the rail and was melted at the point of contact. The end against the pole was also melted and the assistant's thumb and forefinger were severely burned.

The superintendent of the electric railway was notified and sent men at once to investigate the cause of the grounding of the current. Yours truly,

A. J. Gavett.

Plainfield, N. J., June 22, 1896.

(The accompanying sketch was drawn from the pieces of tape sent by Mr. Gavett. The pieces are blued over part of their length and show marked evidences of the extreme heat to which they were subjected.—Ed.)



STEEL TAPE MELTED BY ACCIDENTALLY TOUCHING TROLLEY RAIL WHILE BEING HELD AGAINST IRON TROLLEY POLE.

A Neglected Formula in Trigonometry.

Sir:—The following formula, applicable to the three sides and one angle of a plane triangle:

$$c^2 = a^2 + b^2 - 2ab \cos C \qquad (1)$$

or,

$$\cos C = \frac{a^2 + b^2 - c^2}{2ab} \qquad (2)$$

(in which a, b, and c are the lengths of the sides and C the angle opposite side c) is familiar to the student of applied mechanics on account of its use with the parallelogram of forces, or of velocities. In case a, b, and c are given and C is the quantity sought, it would seem to be the most convenient formula to use, instead of the indirect relation necessitating the preliminary determination of the sum of the three sides and the difference between that sum and each of the sides, with the result that only the half angle is found, instead of the whole angle.

It is a matter of some surprise, therefore, that this formula, (1), is not to be found in engineers' pocket-books published in the United States, although given in foreign publications (for example in Weisbach's "Ingenieurs Taschenbuch" and in "Huette").

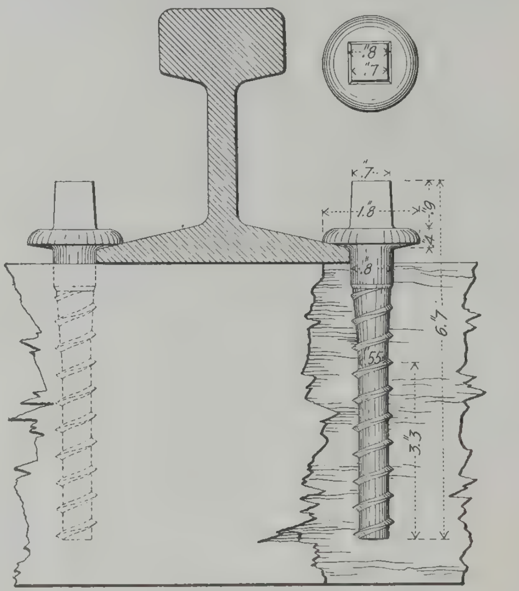
Only a few months ago a gentleman on the Pacific coast, in a letter to the writer, stated a modified form of formula (1) as original with himself, and inquired if it was not new, since he had been unable to find it in Haswell's Pocket-Book, and thought it simpler than those given in that work. It seems worth while, then, to call attention to the formula in your columns.

Sincerely yours, I. P. Church.

Ithaca, N. Y., July 4, 1896.

The Need of Improvement in Rail Fastenings.

Sir: The information on the present standards of American railroad tracks, contained in the articles and tables given in your issue of June 25, is not only interesting but of great value, and you deserve the thanks of all concerned with railroad construction and maintenance.



A Screw Spike Rail Fastening.

I strongly sympathize with your opinion as to the very unsatisfactory character of the ordinary spike as a rail fastening. To one who has observed with any care the condition of the track on even our best lines and noted the fact that hardly more than one-third of the spikes are effective to hold the rails down to the tie, or to do more than to keep them from moving sideways, nothing is more surprising than the continued use of such spikes. In this respect our railways are far behind those of Europe. Either the English bolt and treenail, used with their chairs and double-headed rails, or the Continental screw spike, used with the flat-footed rails like ours, is far better. The latter, the screw spike, is worthy of our special attention. For while it would cost somewhat more at first, it is more durable, as it can be drawn and replaced or used over again without injury to either the spike or the tie, and has the further capital advantage of having a holding power at least double that of the common spike. Its use would save many rail braces, and many ties which are now spoiled by old spike holes. Being unpatented and unpatentable it cannot command the services of enterprising agents to urge its introduction, but even without this, its great merits ought to secure its adoption on all first-class railways.

To make more clear the special features of the screw spike I enclose a blue print of a design, made several years ago, which follows very closely that of the spikes in common use on the Continent—particularly in France.

A Novel Scheme for Power Transmission.

Sir: I have recently devised a very novel system for the transmission of large amounts of power over long distances, which seems to me to have much merit. The system I propose is hydraulic transmission under very high pressure, say 5,000 lbs. per sq. in. Under this pressure it will be readily understood that a very small amount of water will transmit a large amount of power. The difficulty has been, however, that if such water is carried in metal pipes, they must be very thick and costly to withstand the enormous pressures, and as the system only becomes economical compared with electrical transmission when large conduits are used, the use of metal pipes is not feasible. Now, what I propose is to build a tunnel in solid rock for conveying water under high pressure, make it water tight by putting in a continuous lining of metal of moderate thickness, and rely for strength entirely on the solid rock in which the tunnel is built.

To show an application of this system I have taken the transmission of power from Niagara Falls to New York as an example. Call the distance 320 miles. A 30-ft. cylindrical tunnel with water moving through it at 4 ft. per second would give a flow of 2,800 cu. ft. per second. At a pressure of 300 atmospheres this would furnish in round numbers 2,500,000 HP. The loss of pressure in the 320 miles at the low velocity above given would be only 3.3% Estimating the cost of such a tunnel at $60 per lineal foot, its total cost would be about $100,000,000, and with 10% of this sum for interest and depreciation, the annual cost per 24-hour horse power would be only $4. One dollar per horse power per annum would pay for the hydraulic machinery required.

I have filed a caveat on the above system of power transmission.

Very respectfully,
Charles Steiner.

July 14, 7896.

(Our correspondent evidently does not hesitate at large figures.—Ed.)

The Spread of Dry-Rot.

Sir: I would like to hear your opinion, or that of some readers of Engineering News, about the character of dry-rot as a defect in lumber. The Encyclopedia Brittanica, treating of this subject, says it is a disease "apparently of an infectious character." If this is true, it would appear that timber having a defect of this nature, in the least degree, is unsuited for use in any permanent structure; as it is only a matter of time before the entire body of such sticks, thus affected, will be reduced to the same condition.

The question which, at present, concerns me, is this: Will heavy beams or girders of Southern hard pine, when used for inside work and occupying a well-ventilated situation, deteriorate from a small patch of "dote" or dry-rot such as is frequently found in such timber, at the butt end, and which otherwise, or for present purposes, is thoroughly acceptable for its intended use?

I am satisfied similar lumber is constantly used in buildings, and if any of your readers have positive knowledge that lumber of this kind deteriorates more rapidly, under favorable conditions, than sticks not affected; or if such, after years of use, show no apparent spread of the decay, I should for one be glad to hear their testimony.

A. F. W.

Centreville, R. I., July 8, 1896.

(We referred the above letter to the Division of Forestry, at Washington and have received the following reply:—Ed.)

Sir: In reply to your favor of the 11th instant, addressed to Mr. Fernow, who is absent on an extended tour through the West, permit me to say that the probability of dry rot spreading in beams of Southern hard pine when used for inside work in a well ventilated situation is very slight. As your correspondent is doubtless aware, dry rot is a form of fungus, being one of many different genera which grow in the inter-cellular spaces of timber, forming masses of extremely minute threads which penetrate in all directions, practically filling up the cell cavities and eating up, as it were, the cell walls, leaving a mass of dead and dried up threads of the wood material behind, after they are killed or have finished their work. At particular places thousands of these threads come to the surface and aggregate in a crack of the wood forming the whitish or colored bodies which we see as toadstool, bracket funges, etc. These are fruiting bodies which give rise to spores corresponding to the seed of higher plants. These fungi require quite an amount of moisture for their growth, especially at the start, and therefore well seasoned wood is not attacked, and they can even be killed, and usually are, and the "dotage" stopped by drying the timber thoroughly, preferably submitting it to a dry kiln treatment, where the heat will not only kill the fungi and spores but the seasoning will prevent further attacks.

There is little doubt that doty spots are easier of attack and, therefore, endanger the timber to some extent, but if well dried and placed in a dry, well ventilated position, the progress will stop.

Trusting that these notes will be of interest to you, I am, Yours respectfully

Charles A. Keffer,
Acting Chief, Division of Forestry.

Washington, D. C., July 13, 1896.

The Advantages and Disadvantages of a Steam Pile-Driving Hammer.

Sir: I have had occasion recently to use one of the Vulcan Iron Works steam pile driving hammers on the work under progress at the foot of Perry St., North River, N. Y., for the Department of Docks, and my observation of its use and progress in the cheapening of the cost of labor in driving through hard material, as compared with the drop hammer, is such that I feel confident it is only a question of time when, for specific cases, with a few improvements which can readily be made, a steam hammer will become universal, if the prejudices and fear of handling one can be overcome by those who are willing to try it and be benefited thereby.

The driving in the above locality is very hard, the bottom consisting of a 10-ft. layer of cobble stones, the largest being 6 ins. diameter, from 20 to 30 ft. below mean low water, and below that layers of very fine sand, coarse gravel and sand gravel alternate until rock or boulder is reached at a depth of about 90 ft. below mean low water, as shown by test borings.

With the drop hammer 12 piles, 9 in a row, from 2 ft. 3 ins. to 3 ft. c. to c., was considered a very good day's work (of 10 hours) with a crew of ten men. The pile dimensions averaged as follows: point 8 ins., butt 16 ins., length 55 ft. to 60 ft., and took an average of about 175 blows of a 3,300-lb. hammer falling 10 ft. Fifteen blows to the minute was a good average when working, the piles penetrating to from 43 to 50 ft. below mean low water.

With a Vulcan hammer of 8,400 lbs., the piston weighing 4,000 lbs. and having a 42-in. stroke, we were enabled to drive at the rate of 18 piles a day, two rows, and regulate and stay lathe them, the hammer striking 60 blows to the minute and some of the piles taking over 1,200 blows, without a sign of the head being broomed.

The steam hammer can be worked with from two to three less men in a crew than the drop hammer. The principal faults noticeable are that it is almost impossible and certainly not practical with economy to drive crooked piles, and that there is a great tendency to lose overboard the "saucepan" or hood which fits over the head of the pile when it has been trimmed to fit the hammer, which also wears out very quickly. A delay of from 2 to 5 minutes was caused by the steam condensing in the hose pipe leading to the hammer when it was hoisted aloft, a "U" being formed, but this is only a mechanical defect which can easily be remedied. After a pile is once placed, headlines can be dispensed with and the pile is more rapidly and truly driven to place than with the drop hammer. The use of this hammer by the Department of Docks was experimental and had to be stopped after about 75 piles had been driven owing to the fact that the "saucepans," of which there were only two, had worn out. Yours truly,

Eugene Lentilhon,
Assoc. M. Am. Soc. C. E.

New York, July 20, 1896.

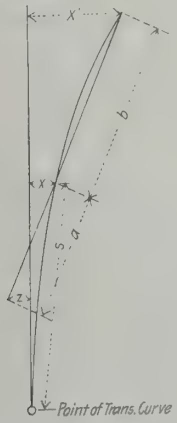
The Cubic Parabola as a Transition Curve for Street Railways.

Sir:—While engaged in business in Pittsburg, Pa., last year I had occasion to establish the alinement of an electric railway, and found in the cubic parabola an easy solution to a seemingly difficult problem. An explanation will be of interest and possibly of benefit to some of your readers.

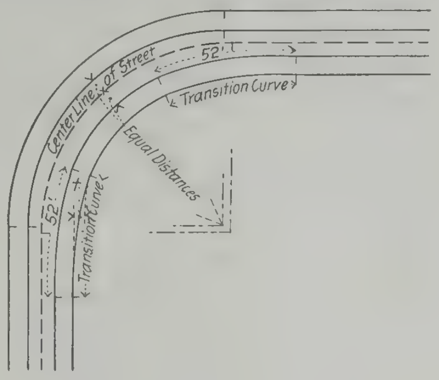


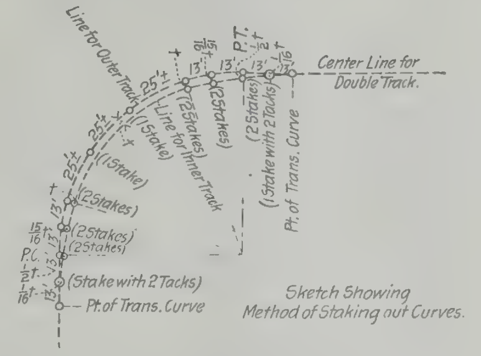
The city of Allegheny straightened, widened, graded and paved Perryville Ave., necessitating the complete rebuilding of the Pleasant Valley Ry. Co.'s line on that street. The avenue is a long and important thoroughfare; as it runs in many places along steep hillsides, requiring heavy retaining walls on both sides, its width was restricted to 60 ft., and at the southern end to 50 ft.; 32% of the alinement is curved; the total curvature amounting to about 1,600°. The radii of curves vary from 50 to 573 ft. In view of the narrowness of the street and the large amount of travel over it, the City Engineer fixed the distance between centers of tracks on tangents at 8 ft. 6½ ins., leaving a clearance of only 6¼ ins. between cars, but allowing the tracks to be spread sufficiently on curves to give the same clearance, but no more; requiring, however, that the tracks should follow approximately the line of the street and that a nearly equal distance should be maintained between track and curb on both sides.

The largest cars in use on this line are 30 ft. long over all; length of car body 22 ft.; maximum width 8 ft. 0¼ in. The cars are mounted on single trucks, with a wheelbase of 8 ft.

It is evident that no arrangement of simple curves would allow the cars to pass at the P. C.'s and P. T.'s and that any arrangement of compound curves would either make too much difference between the alinement of street and track, or would greatly complicate calculation and field work and add to the perplexities of the track foremen. I used the following comparatively simple method to fulfil the complex conditions:

The tracks were made concentric, being spread sufficiently to allow for the "overhang" of the cars; the outer track was made a simple curve, but a cubic parabola was introduced at each end of the inner track; the P. C. and P. T. of the outer track were moved toward the P. I. from the P. C. and P. T. of the street alinement, enough to make the two tracks equidistant from the center of the street at the middle of the curve.





Sketch Showing Method of Staking out Curves.

Approximately $t = \frac{l^2}{8R}$, t being the distance the tracks are spread, or the offset of the inner track, from the tangent to the regular curve produced; l the length of the car, and R the radius of curvature. I took l = 30 in order to "steal" a factor of safety, although l = 22 would have been theoretically correct, as the platforms of the cars are much narrower than the car bodies.

For the length of the cubic parabola (L)

$$\frac{3t}{\frac{1}{2}L} = \frac{\frac{1}{4}L}{R} \text{ or } L = \sqrt{24\,t\,R} \text{ (approximately)}$$

$$\text{or } L = l\sqrt{3}, \text{ a constant for all radii.}$$

Substituting l = 30, L becomes 51.96. Using l = 22, L would become 38.10.

I staked out the outer curve, using two chords of 13 ft. at each end, and dividing the rest of the curve in equal chords of as nearly 25 ft. as possible, for the convenience of the trackmen. Two stakes at 13 ft. and 26 ft. from tangent point, were also put in on tangent. Additional stakes were set by offsets from both tangent and curve for the parabolic portion of the inner curve, but no stakes were necessary for the circular portion.

The trackmen found no difficulty, after the first trial, in bending the rails to a parabolic curve; they began with the sharper end of the curve, with the bender set the same as for the regular curve, and loosened the screw each time the position of the bender was shifted.

To determine the minimum clearance between cars on any curve, and the extent to which this solution is applicable, let

a = distance from end of car body to axle,
b = distance between axles,
s = distance from pt. of trans. curve to nearest axle,
z = offset of end of car body from position on tangent,
x = offset of first axle from tangent,
x¹ = offset of second axle from tangent,
k = a constant, depending on nature of cubic parabola.

Then $x = ks^3$

and $x^1 = k(s+b)^3$

and $z = \frac{a}{b}(x^1 - x) - x$

or $z = \frac{a}{b}x^1 - \frac{a+b}{b}x$; substituting values for x and x^1,

$$z = k\left[\frac{a}{b}(s+b)^3 - \frac{a+b}{b}s^3\right]$$

or $z = k(3as^2 + 3abs + ab^2 - s^3)$.

To find a maximum value of z

$$\frac{dz}{ds}\quad k$$

or $s = a + \sqrt{a(a+b)}$

and $z = k\left[(a^2+ab)(2a+b+2\sqrt{a^2+ab})\right] =$

$$ka(a+b)(\sqrt{a}+\sqrt{a+b})^2$$

but $k = \frac{x}{s^3} = \frac{4t}{L^3}$

hence $z = \frac{4t}{L^3}a(a+b)(\sqrt{a}+\sqrt{a+b})^2$

and for L = 51.96, a = 7, b = 8, z = 0.127t or $\frac{7.6835}{R}$

the clearance of tangent being 6¼ ins. = 0.52 ft.

the minimum clearance is 0.52 — 0.127 t, or $0.52 - \frac{7.6835}{R}$

Substituting 0.52 for z, we get R = 14.77, the smallest radius to which this solution could be applied. As the minimum radius on this line was 50 ft., the solution was therefore applicable in every case. Yours truly,

Jenks B. Jenkins, C. E.

New York city, June 11, 1896.

◆

Notes and Queries.

R. S. M. asks which is the better practice in lettering maps, to say "Scale: 500 ft. = 1 in.," or "Scale: 1 in. = 500 ft.?" So far as we are aware the former expression is more commonly used on maps and the latter on drawings of structures, machines, etc., especially detail drawings to a large scale. Still another way to designate a scale, and one which has much to commend it, is to say "Scale = $\frac{1}{500}$."

R. W. W., Shreveport, La., asks which side up an oak tie should be laid, which has one side flat for its full width and the other side has its corners rounded off. The roadbed is dirt. We refer the query to our readers.

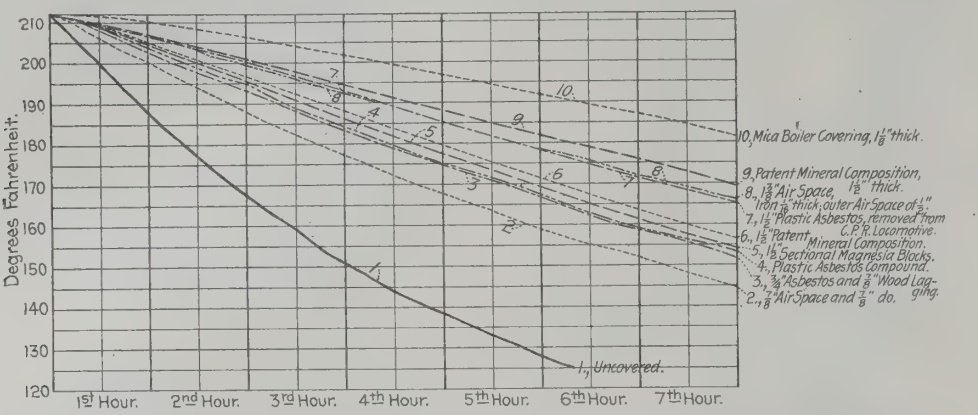
TESTS OF NON-CONDUCTING MATERIALS FOR BOILER COVERINGS.

The Canadian Pacific Ry. Co., in April last, undertook a series of experiments to determine the comparative merits of various different coverings for steam boilers, to determine which was the best to adopt as a lagging for the boilers of its locomotives. Among the materials tested was a new composition made by the Mica Boiler Covering Co., of Toronto, Ont., which showed in the test remarkable insulating qualities, materially exceeding those of any other non-conductor tested, as will be seen by the lines on the accompanying diagram.



EXPERIMENTS TO DETERMINE RELATIVE HEAT INSULATING POWER OF VARIOUS BOILER COVERINGS.
Made at the Canadian Pacific Ry. Shops, April, 1896, R. Atkinson, Mechanical Superintendent.

Note: In all the tests but Nos. 9 and 10, to the covering noted above an outer coat of Russia iron was added.

The method of testing was as follows: An iron tank was entirely covered with the non-conductor to be tested, and was then filled with water which was heated to a temperature of 212°. The tank was then allowed to cool and the temperature of the water in its interior was taken at intervals, and the diagram was constructed in accordance with these results. Simultaneous observations were taken of a thermometer in the room where the tank was located, and these results were also plotted, but as they showed the atmospheric variations to be too small to have any appreciable effect on the results we do not reproduce this diagram, merely remarking that these external temperatures varied between extremes of 70½° and 87°, but in most of the tests the range was much smaller than this.

The tank used in tests 1 and 2 was 14 ins. high and 13⅜ ins. in diameter. That used in tests 3, 4 and 5 was of the same diameter and 15¼ ins. high. That used in tests 6, 7, 8, 9 and 10 was 13⅜ ins. diameter and 13⅝ ins. high. While the tests should properly have all been made with the same tank, the difference in size does not appear to have been great enough to materially affect the results.

The fact above stated and the diagram from which ours is redrawn are published in the "Canadian Electrical News," which presents also the following table, showing the loss of heat in degrees in the fifth hour per degree of difference of temperature between the tank and the surrounding atmosphere:

Covering.	Mean temp. during 5th hr.	Diff. bet. tank and air, deg.	Loss, 5th hr. Actual, deg.	Loss, 5th hr. Diff. of temp., deg.
None	133½	55½	11	0.198
Asbestos composition	163½	85½	9	.105
Sectional magnesia	181¾	103¾	7	.0674
Wood lagging and air space	.81¾	103¾	7	.0674
Asbestos and wood	185	107	6	.056
Mica	194½	116½	5	.0428

It will be seen from the above that the heat escaping from the bare tank was 1.88 times that escaping through the asbestos compounds, 2.92 times that lost through the sectional magnesia blocks, or the wood lagging and air space, 3.53 times the loss through the asbestos and wood covering, and 4.62 times the loss through the mica covering.

The mica covering has been placed upon the market quite recently, and, we are informed, consists of leaves or films of mica separated by minute corrugations so as to make a great number of air cells. Any of our readers interested can doubtless obtain samples by addressing the manufacturers, the Mica Boiler Covering Co., 9 Jordan St., Toronto.

THE EFFECT OF RETARDERS IN FIRE TUBES OF STEAM BOILERS.*

By Jay M. Whitham,** M. Am. Soc. M. E.

The trials were conducted on a 100-HP. horizontal tubular boiler at the Sutherland Ave. Station of the Philadelphia Traction Co., Philadelphia. The purpose of the trials was to ascertain under what condition, if any, retarders in the fire tubes would add to the efficiency of the boiler.

Dimensions and Proportions of Boilers and Setting.

Boiler shell	60 ins. × 20 ft.
Tubes (44)	4 ins. × 20 ft.
Grate surface	26.7 sq. ft.
Water-heating surface	1,137 sq. ft.
Ratio of heating surface to grate area	42.6 to 1
Steam-drying surface in top of shell	150 sq. ft.

Boiler set with a return pass over the top.

Ten such boilers are connected to a brick stack 10 ft. diameter by 175 ft. high. During the tests from four to seven of these boilers were run in connection with the boiler tested. On certain tests retarders were used in the tubes. These were made of loosely fitting strips of No. 10 sheet-iron, running the whole length of the tubes, and twisted to a pitch of 10 feet., or making two entire convolutions in the length of the tube.

The tests were conducted according to the methods advised by this Society, and all instruments used were standardized. L. Kennedy, a careful and skilful fireman, fired on all the tests. The boiler tubes were clean at the beginning of each test, while the boiler was fairly clean on the water side. Several of the tests were duplicated in order to make sure that no error existed.

Results of the Trial.

Coal.—The coal was practically uniform in quality on all the tests. The percentage of ash and refuse varied from 8.72 to 4.25%.

Drafts.—The draft was measured in the furnace, in the front connection, and in front of the damper at the rear end of the return pass over the top of the boiler. The damper was manipulated so that the draft would be just sufficient to burn coal for the power desired to be developed on each test.

Table I. compiled from the results obtained in the tests should be valuable in predicting the drafts needed for any rate of combustion from 5 to 40 lbs., an hour per sq. ft. of grate with bituminous coal, natural draft and horizontal tubular boilers, while it should be of use also with water-tube boilers.

TABLE I.—Draft Required for Boiler with Various Rates of Combustion.

	Resistance due to				Total draft			
Pounds of dry coal burned an hour per sq. ft. of grate.	Furnace draft.	Pass under boilers and thro' tubes; no retarders.	Retarders in tubes.	Pass over top of boilers.	No. retarders; no return pass.	With retarders; no return pass.	Top pass; no retarders.	With top pass and retarders.

25	0.27	0.22	0.19	0.06	0.49	0.68	0.55	0.74
28	0.29	0.24	0.27	0.07	0.53	0.80	0.60	0.87
30	0.30	0.27	0.31	0.07	0.53	0.88	0.64	0.95
34	0.32	0.31	0.38	0.08	0.63	1.01	0.71	1.09
36	0.33	0.34	0.40	0.08	0.67	1.07	0.75	1.15
40	0.36	0.38	0.46	0.08	0.74	1.20	0.82	1.28

Quality of Steam.—The steam was practically dry for every condition of the tests, however much, the boiler was pushed in capacity. This is due to the large liberating surface in boiler and the use of dry pipes.

Economic Evaporation.—Table II. shows tests with and without the use of retarders.

The advantage due to retarders is as high as 18% when the boiler is greatly forced. The temperature of the waste gases is always less when retarders were used. Herein lies the advantage of retarders. Their use renders more efficient the heating surface of the tubes, enabling the gases to be reduced in temperature, and the same capacity of boiler to be developed with a less expenditure of fuel.

The accompanying cut shows at a glance the usefulness of retarders. A reduction in temperature of the waste gases shows at once a decrease in the coal consumption, as follows:

52	HP., gases reduced	20° F., fuel saving	0.0%
75	" " "	53° " " "	0.0%
100	" " "	32° " " "	3.2%
125	" " "	46° " " "	4.0%
150	" " "	19° " " "	3.3%
170	" " "	59° " " "	3.6%
200	" " "	36° " " "	4.1%
225	" " "	26° " " "	8.6%
239	" " "	123° " " "	18.4%

Variation of Economy with Capacity.—By Table II. we see that the 100 HP. boiler, rated on 11.37 sq. ft. of water-heating surface to the horse-power, could easily develop over 200 HP. At its rated power 3.03 lbs. of water, from and at 212° F., were evaported per hour, yet there was no difficulty in evaporating 7.26 lbs. to 1 sq. ft., or in getting a horse-power on 4.76 sq. ft. of heating surface.

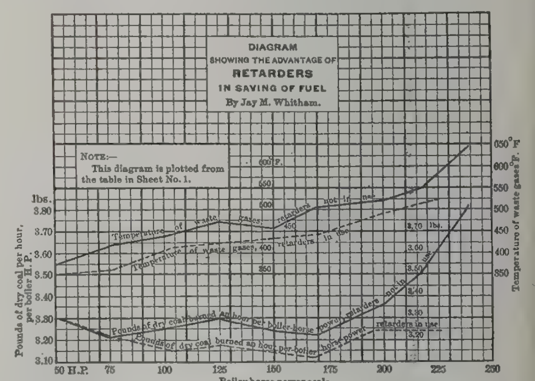

Diagram Showing Fuel Saving due to the Use of Retarders in Steam Boiler Tubes.

TABLE II.—Results of a Series of Trials on a 100-HP. Horizontal Tubular Boiler, to Determine the Value of Retarders in the Tubes.

Duration of trial, hours	9	9	9	9	9	9	9	9	9.1	9	9	9	9	9	9	.9	9

---

* Condensed from a paper presented at the St. Louis meeting of the American Society of Mechanical Engineers.

** 131 South 3d St., Philadelphia, Pa.

The cost in fuel of a horse-power was as follows for the tests made without the use of retarders:

Boiler, HP.:	52.4	74.6	99.7	125.3	150.0	169.6	199.7	217.4	239.0
Dry coal per HP., lbs.:	3.30	3.21	3.25	3.30	3.24	3.22	3.36	3.51	3.82

These results show that there is practically no change in the economic workings of the boiler when run at from 50% below to 70% above its rating, i. e., when making a horse-power an hour on anywhere from 21.7 to 6.7 sq. ft. of heating surface.

The cost of fuel per horse-power was as follows for the tests made with retarders in the tubes:

Boiler, HP.:	52.4	77.3	104.2	127.5	148.6	169.1	197.3	226.1
Dry coal per HP., lbs.:	3.30	3.21	3.15	3.18	3.14	3.11	3.23	3.23

It is therefore evident that retarders enable a boiler to be run as economically on 5 sq. ft. of heating surface to the horse-power as on 21.7 sq. ft., or, practically, as on any number of square feet between these limits.

Conclusions.

1. Retarders in fire tubes of a boiler interpose a resistance varying with the rate of combustion.
2. Retarders result in reducing the temperature of the waste gases, and in increasing the effectiveness of the heating surface of the tubes.
3. Retarders show an economic advantage when the boiler is pushed, varying in the tests from 3 to 18%.
4. Retarders should not be used when boilers are run very gently, and when the stack draft is small.
5. It is probable that retarders can be used with advantage in plants using a fan or steam blast under the fire, or a strong natural or induced chimney draft, when burning either anthracite or bituminous coals.
6. Retarders may often prove to be as economical as are economizers, and will not, in general, interpose as much resistance to the draft.
7. Retarders can be used only with fire tubular boilers.
8. The economic results obtained on the boiler tested are ideal, showing that it was clean, the coal good in quality, and the firing skillful. With retarders the tubes are more effectively cleaned than without their use.
9. The tests prove that the marine practice of using retarders is good, and that the claim, often advanced, that they show from 5 to 10% advantage, holds, whenever the boiler plant is pushed and the draft is strong.

Discussion.

Charles Whiting Baker.—It is a rather curious fact that while "retarders," as they are called, have been used more or less for several years, and, in some instances with very notable advantage, Mr. Whitham's paper, so far as I am aware, is the first extended account of their use and their advantages which has appeared in technical literature, although of course allusions to their use in connection with various steam plants have been made in various papers.

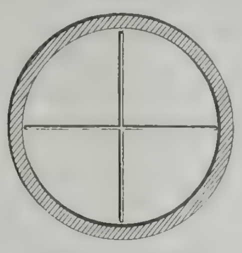
Another curious fact is that the action of "retarders" in the flue has been generally misunderstood, as is indicated by their name. The "retarder" does of course obstruct and "retard" the flow of gas through the flue; but this is by no means the purpose for which it is placed there. If it were desired simply to make the hot gases flow more slowly through the tubes, the simplest and best way is to check the draft by dampers in the chimney or at the ash pit.

What the so-called retarder does that is beneficial is to increase the amount of heat transmitted to the tube surface from the hot gases; and it does it in two ways. First, by a mixing action upon the gas in the tube. The friction upon the surface of the retarder aids in stirring up the gas in its passage through the tube and mixing the hot gas at the center with the cold film next the surface of the tube. Also in every horizontal tube there is a tendency for the gases to be cooler in the upper part of the tube and hotter in the lower, for the upper half of the tube extracts heat far more readily from the tube than the lower half. The twist of the retarder has the effect of repeatedly "turning over" the gas in the tube as it flows along.

In the second place the retarder acts by direct radiation of heat to the tube surface. While this action may not be apparent at first sight it is of such importance that it should be clearly understood. To this end the fact should first be realized that the temperature of the tube surface exposed to the fire in any steam boiler is practically the same as that of the water in contact with it, no matter what the temperature of the gases on the other side. (We, of course, suppose the tube surface to be clean.) The reason is that water absorbs heat many times as rapidly as gas. As experimental proof I may add that in a small boiler filled with cold water I have often seen dew collect and stand in beads upon the fire side of the tube when a current of gas at a temperature of over 1,000° F. was passing through the tube.

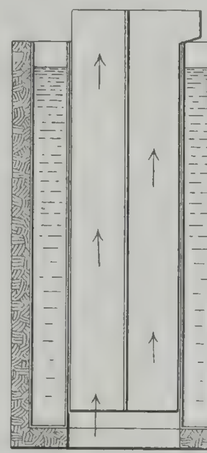
The rate of absorption of heat by boiler heating surface then, depends almost entirely on how much heat we can impart to this surface on the fire side. In the ordinary boiler tube, heat is imparted to the surface of the tube only by the contact of the hot gases. Now suppose we place in the tube any solid body, of any shape whatever. Manifestly, as it is surrounded and bathed on all sides by gases at a temperature of say 1,000°, it will, if it loses no heat, soon become of the same temperature as the hot gases. Suppose the surface of the tube is at a temperature of 300° F. Then we shall have these two surfaces only an inch or two apart and a difference of temperature between them seven times as great as exists between a very cold winter day and the maximum heat of summer. Under these circumstances, of course, the hot body at the center of the tube will energetically radiate heat to the walls of the tube and will materially increase the rate of heat transmission.

The amount of radiation in any given tube depends on the area of radiating surface and on the difference in temperature between the radiating surface and the surface of the tube. A radiator of cross shape, like that shown in the accompanying cross section of a tube, has a radiating surface nearly 1½ times as great as the inner surface of the tube, and experiment shows it to radiate nearly twice as much heat in a given time as a flat strip of a width equal to the tube diameter.

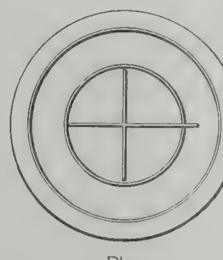


Cross Section of Boiler Tube With Radiator Inserted.

I have made numerous experiments to test the efficiency of radiators, with the apparatus shown in the accompanying sketch. It represents a section of a single tube of a vertical boiler. The water space surrounding it is well protected by a non-conductor, so that the loss of heat is very small. Through the tube a current of hot gas is caused to flow from a lamp, gas jet, or other suitable source and the amount of heat transmitted to the water in a given time is measured. The test is then repeated under identical conditions, except that a radiator of the form shown above is placed in the tube. The increased amount of heat transmitted to the water is taken as the amount due to the radiation from the internal piece.



Section.



Plan.

Apparatus for Measuring Increase in Transmission of Heat to the Tube Surface due to Radiation.

Experiments with this apparatus show the following general results:

(1) That the percentage of increase in heat transmitted due to radiation increases with increase in temperature of the gases passing through the tube.

(2) That the percentage of increase in heat transmitted due to radiation is larger in vertical tubes than in horizontal, on account of the fact that a given area of heating surface in a horizontal tube absorbs heat faster by direct contact with the gases than the same area in a vertical tube.

In general, the experiments showed that with vertical tube heating surface and gas passing through the tubes at a temperature sufficient for the tube to transmit 1,000 to 3,000 B. T. U. per sq. ft. per hour, the insertion of a radiator would cause an increased heat transmission of 200 B. T. U. to 1,200 B. T. U. per sq. ft. of radiating surface per hour; or, in other words, the insertion of a radiator in that part of a tube in which the gas is of high temperature appears to increase the amount of heat absorbed from 20 to 40%.

These experimental figures for the amount of heat transmitted by a radiator in a tube are corroborated by the figures for relative radiation and convection given by D. K. Clark in his treatise on the steam engine, p. 68, et seq.

The radiators possess the advantage over the spiral retarders described by Prof. Whitham, that they do not obstruct the draft to so great an extent, and they interfere less with the cleaning of tubes with the steam jet blower.

Experiments on actual boilers indicate that either device is most useful on boilers with short tubes, of not too small diameter and with an abundance of draft. With either device the tube surface must be kept clean, otherwise the increased efficiency will soon disappear, as is the case with the Serve ribbed tubes when care is not taken in this respect. It appears likely that either of these devices may be used with especial advantage, therefore, where a clean fuel like gas or oil is used. Another application of these devices which appears to have promise is to the tubes of vertical boilers of the Corliss or Manning type. An objection to these otherwise excellent types of boilers is the very high head room that is required to get in tubes long enough to extract the heat from the gases with reasonable completeness. By the use of some device to increase the tube-heating surface efficiency, a shorter tube should be permissible, with a consequent reduction in the height of the boiler.

The economic gain by the use of either radiators or retarders depends entirely on the temperature at which the boiler is discharging its hot gases. In general it may be assumed that every 100° reduction in the temperature of the waste gases represents from 5 to 10% saving in fuel.

In general it will not usually be found worth while to introduce either retarders or radiators in the tubes of any boiler unless the thermometer shows its hot gases to be discharging at a temperature of over 550° F.

I notice among Mr. Whitham's conclusions the statement that: "Retarders can be used only with fire tube boilers." This doubtless refers to the proposition to place retarders inside the water tubes, which is absurd on its face to any one correctly understanding the action of the retarders. The use of radiating bodies of extended surface, however, in the gas passages between the tubes of a water-tube boiler, should in theory at least give the same advantage as in the case of fire tubes. Two methods for effecting this radiating action devised by the writer may be found by reference to U. S. patents Nos. 529,997 and 559,021.

◆

A 1,000 HP. VERTICAL TUBULAR BOILER has just been placed in the Cortlandt St. Station of the New York Steam Co. It weighed 119,000 lbs., and was 23 ft. long and 10 ft. in diameter. Its 220 steel flues are each 5 ins. diameter and a 7-in. circulating tube surrounds each flue and extends from near the bottom of the boiler to near the water line. The boiler was built by the Edgar Boiler Co., of Warren, Pa.

◆

AMERICAN AGRICULTURAL MACHINERY is finding a market in Ireland. U. S. Consul Newton B. Ashby, of Dublin, in commenting on the exhibits at the recent show of the Royal Dublin Agricultural Society, says that the English and Irish agricultural tools are as a rule much heavier in make and more clumsy in appearance than the corresponding American tools. He believes that it would be well to study the prejudices of the farmers and build heavier machines for sale in this market.

◆

NEARLY $400,000,000 is the total of British capital which was invested in various enterprises floated on the London stock market during the first six months of 1896, according to the London "Economist," the actual figures being £79,494,000. Of this sum about £11,000,000 was invested in loans of foreign governments, and about an equal sum, it is amusing to note, in companies formed to manufacture cycles and cycling appliances.

◆

THE EFFECT OF ELECTRICITY ON PROJECTILES while in flight has been illustrated by some recent trials of the Swiss army rifle. The "Journal de Geneve" states that during this trial strange deflections of the bullets were noticed that could not be accounted for until it was discovered that an electric line paralleled the range. Experiments were made by building a line of four steel cables the full length of the range, 780 ft., and about 120 ft. from it. When these cables carried a heavy current of electricity the lateral deflection for this distance was about 70 ft. For a longer range the deflection was much increased; with artillery and a range of 9,000 ft. the deflection from the true line is claimed to reach the enormous amount of 14°. It is not stated whether the deviation is toward or away from the electrical current.

ELECTRICAL SUBWAYS are to be built by the city of Minneapolis in all streets which are to be paved with asphalt. Space will be provided sufficient for the use of the city and for all companies having electric wires of any sort in the streets. The work will be in charge of Mr. F. W. Cappelen, city engineer, and is expected to cost about $90,000.

ELECTRIC MOTORS have been installed to operate the swing span of the new highway bridge across the Connecticut River, from Middletown to Portland, Conn. Four General Electric 800 motors are used, one of which swings the span, two others operate each the lifting mechanism at one end of the span, and the fourth is held in reserve. The span is 450 ft. in length, and we are informed that previous to the installation of the electric motors 15 men were required to start the bridge and 8 to swing it.

A PNEUMATIC TUBE POSTAL SYSTEM is reported to be contemplated in Philadelphia to connect the main post office with the sub-stations. A half-mile tube, 6½ ins. diameter, from the Philadelphia Stock Exchange to the post office has been in successful operation for some years.

THE EXPOSITION BUILDINGS, AT ATLANTA, GA., have been badly injured by prolonged and heavy rains. The manufactures and liberal arts building is almost totally destroyed. It had a flat gravel roof on which the water collected, owing to stoppages in the water pipes, and the weight of water caused its collapse.

THE ARCHITECTURAL APPEARANCE OF THE NEW East River Bridge is engaging the attention of the Commission in charge of the work. Mr. Selim H. Peabody, a member of the Commission, proposes the appointment of an architect to co-operate with the Chief Engineer, Mr. L. L. Buck, in designing details of the structure, such as balustrades, lamp-posts, etc., so as to produce the most pleasing effect. The suggestion is an eminently sound one, and it is to be hoped that it may be carried out.

AN ENGINEER CORPS is a novel feature of the staff of Brigadier-General Wheeler of the Illinois Militia. The staff has been organized by Capt. J. I. Kelly, and among its members are Albert F. Reichmann, assistant bridge engineer of the Chicago, Milwaukee and St. Paul Ry.; W. H. Finley, bridge engineer of the Chicago & Northwestern Ry.; C. L. Crabbs, assistant engineer of the Metropolitan Elevated R. R.; Jules Roemheld, Superintendent of Bridges of Chicago; J. W. Crissey, assistant engineer of the Metropolitan Elevated R. R.; and Fred E. Mather, architect. The corps is expected to become proficient in the construction of fortifications, military bridges, etc.

A CODE OF ETHICS was adopted by the Denver chapter of the American Institute of Architects at its meeting on July 6. The following extracts from it are published in a Denver daily paper:

> No member should enter into partnership, in any form or degree with any builder, contractor or manufacturer.
>
> No member should guarantee an estimate or contract by personal bond.
>
> It is unprofessional to offer drawings or other services "on approval" and without adequate pecuniary compensation.
>
> It is unprofessional to make alterations or to complete a building in the course of construction designed by another architect, until satisfactory settlement has been made with the first architect, unless dishonest practice on the part of the first architect has been proven.
>
> It is unprofessional to attempt to supplant an architect after definite steps have been taken toward his employment.
>
> No member shall compete in the amount of compensation, or offer to work for less than another, in order to secure the work.
>
> It is unprofessional to work for less compensation than that indicated by the schedule of charges adopted by the American Institute of Architects, which is as follows: For full professional services, including supervision, 5% of the cost of the work. For drawings, specifications and details without supervision, 3½%. For alterations and additions an additional charge to be made, in proportion to the extra labor involved. Necessary traveling expenses to be paid by the client.

TRIPLE SCREWS are to be adopted on two battleships and five cruisers to be built by the German government.

THE LATEST AIRSHIP INVENTOR is one John F. Cooley, of Philadelphia. According to the newspapers he is about to construct "a mammoth 200-ft. air ship, at Charlotte, N. Y." The apparatus is to be of the inclined plane type, propelled by gasoline motors.

THE GALVESTON JETTIES are rapidly approaching completion to the point fixed by the project of 1886, which was the 30-ft. contour. On July 9, according to the Houston "Post," the trestle of the south jetty was within 400 ft. of the proposed terminus and the trestle of the north jetty was 800 ft. from its terminus. The same authority states that whereas the engineer's estimate of the cost of the work in 1886 was $7,000,000, it now appears that the entire work will be completed for nearly a half-million dollars less.

BOOK REVIEWS.

STEEL IN CONSTRUCTION.—Convenient Rules, Formulas and Tables for the Strength of Steel Shapes Used as Beams, Struts, Shafts, Etc., Made by the Pencoyd Iron Works. A. & P. Roberts & Co., Philadelphia, Pa. 12mo; cloth; pp. 232; illustrated.

This is the ninth edition of the familiar little handbook published by the A. & P. Roberts & Co., and like former editions it contains besides tables of weights and dimensions a large number of formulas, rules and instructions for the use of the different shapes in construction. There are numerous cuts in the text and 30 full page plates, and also a very adequate index.

CHEMISTRY AT A GLANCE.—A Study in Molecular Architecture. Issued in Series. No. 1, Oxides. By Herbert B. Tuttle, 131 Lexington Ave., New York. Pamph. 8vo.; pp. 59; 60 cts.

In this pamphlet are given diagrams showing for over 200 chemical substances the structure of the molecules, according to the generally accepted theory of such structure. Those unfamiliar with chemistry may not be aware of the fact that the position of atoms in a molecule may be as important in determining the nature of a substance as the nature of the atoms. Thus alcohol, a liquid, and methyl ether, a gas, have each the same composition and the same chemical symbol ($C_2 H_6 O$).

The knowledge of molecular structure is therefore often very important to a working chemist, and this handy volume will be found convenient by many, we presume, as a work of reference. We do not see why the author does not give together with his "architectural formulas" the ordinary formulas also. They might be a convenience to some who are not familiar with current chemical nomenclature. For example, the formula given for silicon triethyl oxide, alias silico-heptyl oxide, takes up three-quarters of a page, being an architectural structure, 18 stories high. We find that it contains 30 H's 12 C's, 2 Si's and an O. Might not its formula $H_{30} C_{12} Si_2 O$ also be given?

WATER SOFTENING AND PURIFICATION.—The Softening and Clarification of Hard and Dirty Waters. By Harold Collet (Stanhope Water Engineering Co., Limited, London). London: E. & F. N. Spon & Co., New York: Spon & Chamberlain. 12mo.; cloth; pp. 168; 12 illustrations. $2.

This book is almost wholly devoted to water softening, with a little matter relating to the removal of iron and to the clarification of water. The information on clarification is not only meager, but fails to convey an adequate idea of clarification processes, practically ignoring mechanical filtration as practiced in this country.

The author sets forth the chemical and other characteristics of hard water, noting especially the objections to its use for household and industrial purposes. The various chemicals used for softening are discussed and their chemical action stated.

No descriptions of softening plants in actual use are given, but some apparatus for this purpose is described and illustrated. The fact that practically all the devices presented are made by the company with which the author is connected raises the question whether the book is not intended as much as anything else for an advertisement. The name of the author's company follows directly after his own on the title page; the devices described are frankly credited to the company; and the reading matter is followed by advertisements of the company, the only ones in the book.

Much of the information given is of such a character that it would not be affected by the fact that the writer is personally interested in certain processes, but most, if not all, books written under such circumstances need to be read with caution.

DIRECTORY TO THE IRON AND STEEL WORKS OF THE UNITED STATES.—Embracing a full list of the Blast Furnaces, Rolling Mills, Steel Works, Tinplate Works, Forges and Bloomaries; also of all the Wire Rod Mills, Wire Mills, Cut-Nail Works, Wire-Nail and Horse-Nail Works, Car Axle Works, Car Wheel Works, Car Building Works, Locomotive Works, Cast and Wrought Iron Pipe Works, Malleable Iron Works, Shipbuilding Works and Bridge Building Works. To which is added a complete list of the Iron and Steel Works of Canada and Mexico.—Compiled and published by the American Iron and Steel Association, Philadelphia, Pa. Cloth; 8vo.; pp. 334. $6.

This is the thirteenth edition of this well-known directory, which is published every two years, and its scope is pretty clearly shown by the sub-title quoted in full above. Since the edition of 1894 was issued a large number of new enterprises have been undertaken, including a surprisingly large number of sheet mills and tinplate works. The list of malleable iron works is a new feature of the directory. The directory includes 469 blast furnaces, with a capacity of 17,373,637 tons per annum; 505 rolling mills and steel works, of which 463 contain trains of rolls; 4,408 puddling furnaces; 44 standard Bessemer steel works, with 95 converters; 3 Clapp-Griffiths and 4 Robert-Bessemer steel plants, the annual converting capacity of all the Bessemer steel works being 9,472,350 gross tons of ingots and direct castings; 88 completed open-hearth steel plants, and 4 in course of erection; the annual capacity being 2,430,450 gross tons; 35 open-hearth plants prepared to manufacture castings; 45 crucible steel plants; 53 cut nail mills with 4,598 machines; 53 wire nail works; 23 works for rolling wire rods; 73 wire-drawing works; 156 completed plate mills; 69 tinplate works; 23 forges and bloomaries; 74 bridge works; 108 pipe and tube works, 112 car wheel works, etc.

The equipment and capacity of each plant, the date of construction, the names of officers and other interesting information is given. All this matter has been entirely rewritten. The establishments are classified by their products and arranged alphabetically in this classification, while there is an index to the names of works and companies, and to the principal brands of pig iron. The book is well printed and neatly bound, and is an invaluable work of reference for all persons interested in the iron and steel industries.

THE SAN FRANCISCO CONVENTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.

By F. S. Odell, M. Am. Soc. C. E.

The 28th Annual Convention of the American Society of Civil Engineers was held in San Francisco, June 29 to July 2. A nucleus formed by the Eastern members with their families and friends to the number of 28 left Grand Central Depot, New York, on June 22, at 6 p. m. Other members joined the party at various points en route until a very creditable representation gathered at San Francisco.

The details of the itinerary were arranged and the party conducted by Raymond & Whitcomb.

The first stage of the journey ending at Chicago was swiftly accomplished over the New York Central and Lake Shore & Michigan Southern railways. At Chicago a stop of an hour and a transfer to the Chicago, Rock Island & Pacific R. R. was made. The following day, June 24, was passed amid the wheat and corn fields of Iowa and Nebraska, where the luxurious growth of leaf and stalk gives promise of abundant harvests. Another night is passed and the party awakens on the morning of the 25th on the Colorado plains. Either there has been an unusual amount of rainfall in this region this year or man has made great conquests on these arid plains within the ten years since the American Society of Civil Engineers held its convention in Denver. Certainly a very great change is evident since then. Man has taken possession; the whole country is fenced in, cattle and sheep are seen on every side, the slopes appear somewhat verdent and even the little prairie dogs and jack rabbits have mostly disappeared.

The party take a late breakfast at Colorado Springs and go on to Manitou.

If the plains of Colorado have changed, what may be said of the towns? Colorado Springs has become a thriving city, and the Manitou of ten years ago could not be recognized were it not for the unchangeable mountains. A trolley line now makes frequent trips between Colorado Springs and Manitou, running as far up as the Iron Ute Spring. Houses and shops line the street all the way, and, climbing out of the narrow valley, perch in picturesque locations on the mountain sides and cap the summits of the foothills. A good wagon road leads up William's Canon to the Cave of the Winds, and a railway ascends the old Pikes Peak trail to the summit of the mountain.

The party availed itself to the fullest extent of the opportunity to enjoy the wonderful scenery; the canons were diligently explored, the Garden of the Gods was visited, Pike's Peak ascended, a great volume of rarefied air inhaled and quantities of the pungent, sparkling waters imbibed.

Unfortunately for those ascending the 14,200 feet of Pike's Peak, the day was somewhat overcast and the summit enveloped in clouds, but the magnificent views obtained during the ascent and descent, and the exhilaration of the lofty altitude, were considered sufficient compensation. The hours fled all too quickly, and every one regretted that the stay was so brief, as it would take a week at least to thoroughly "do" Manitou.

A good night's rest and the journey is renewed on the 26th by special train on the Denver & Rio Grande R. R. This special train added very greatly to the pleasure of the journey—stops being prolonged at points and places of special interest to the party, while others of less attraction were omitted altogether. At 11 a. m., Pueblo, "the Pittsburg of the West," is reached. Here are abundant signs of progress, hither is brought the product of the mines, iron ores, coal, gold and silver, here the ores are smelted and rolled into commercial forms. Some fine public buildings are noted, among them the State Normal College; also many handsome residences, as well as the remains of some old adobe houses still peopled by Mexicans, a strange blending of ancient and modern life.

From Pueblo westward, the railway follows the Arkansas River, which flows through a broad valley at Pueblo, along which frequent irrigation flumes and ditches are seen leading water from the river upon the arid and parched bottom lands, which at once respond with luxuriant growths of alfalfa, corn and other cereals.

As the train speeds onward the valley contracts, the mountains seem to bar the way and forbid further progress, but the roadway glides around the base of a lofty mountain and makes its sinuous passage along the verge of the river, which has here become a narrow, foaming torrent, occupying the full width of the gorge from which the rocky walls of the cliffs rise almost perpendicular to the height of a thousand feet or more, the climax is reached at the Royal Gorge, where the cliffs on either side approach each other so closely that there is no room for the railway, so the engineers in the original construction bridged the river lengthwise, or, in other words, hung up the railway above the river on long girders suspended from rafters like trusses thrown across the canon and buttressed against the solid walls of the cliffs on either side of the river.

The railway as originally constructed through the canon was narrow gage, but has since been widened to standard, and in the reconstruction it was found practicable to build a heavy retaining wall under the suspended bridges, so now it is more ornamental than useful, but it affords an excellent object lesson of the readiness with which the engineers surmounted a difficult obstacle in a novel and unusual manner, and it is to their credit that if they erred it was on the side of greater security in construction. The scenery at the Royal Gorge and for miles through the canon is wonderful beyond description, the mountains rising almost vertical for thousands of feet, and as the train moves onward, taking various forms, rent by side canons of marvelous wildness and beauty, the traveler is entertained with a kaleidoscopic series of views that can never be forgotten.

At Salida we stop for dinner and then proceed through Leadville, the most westerly town visited by the convention party in 1886. Only a brief stop was made and the ascent was begun to Tennessee Pass at the Continental Divide, which attains an altitude of 10,418 ft., the highest elevation passed over in the train during the trip. The railway passes under the summit through a tunnel, the Arkansas River and the Atlantic slope are left behind, and the descent toward the Pacific is begun. The Eagle River is followed until it empties into the Grand. In the Eagle canon the train is stopped to view some mining operations at the Belden mines. These are very rich gold producing mines, the entrances to the shafts are hundreds of feet up the mountains, where buildings containing the hoisting machinery can be seen. Communication with the valley and railway is had by means of cableways. To the uninitiated it looks like a very improbable place to find precious metals. Further down the valley of the Eagle, large lava beds are seen on the easterly side of the river. Apparently the lava has been forced from fissures in the mountain, as no crater appears. At the Grand another canon is entered, which if not so sublime as that of the Arkansas, is equally wonderful, and by some is considered more beautiful, the cliffs taking the forms of Egyptian architecture and rising into suggestions of temples and theatres, but we are surfeited with mountains and canons, and while the day has been crowded with marvelous scenes and interesting features, all are so wearied that a few hours' rest with a bath in the warm sulphur water and a good supper at Glenwood Springs is most welcome. We find this place a gem set in the mountains, with a commodious and well appointed hotel, ample lawn, verdant with grass and shaded with trees and vines, large bath houses with all the appliances for bathing in luxury. A large swimming pool, fed by a gushing sulphur spring that sends out sparkling crystal water at a temperature of about 120° F.; the water in the pool is kept at a pleasant temperature for bathing by the admixture of a sufficient quantity of cold water. Bathing in the open pool is indulged in at any time of year, even in the coldest of weather and amid snow storms.

Supper is taken at the hotel; a delightful siesta on the veranda, with coffee, cigars and the accompaniments of music and an electric fountain, a dream of delight. Again the cars are taken and the weary members of the party seek their berths. Later the cars are attached to the regular train and the journey is resumed.

The next morning, June 26, the aspect has changed wonderfully; we are in Utah; the mountains are lost to view and barrenness and desolation is all that meets the eye. On these alkali plains, with a scanty growth of sage bush, a solitary coyote, gaunt and ill-favored, gives the finishing touch to a landscape that for dreariness can hardly be surpassed. This continues for miles and miles until the Valley of the Jordan is approached, where, under the influence of irrigation and cultivation, the soil is very productive; grass and grain wave in the meadows, the trees are prolific in fruits, and flowers bloom in the gardens by the roadside.

Salt Lake City is passed with dissolving views of the Tabernacle and New Temple, the latter a notable work of architecture. Thus far the genius of these Mormon architects seem to have been expended on the ecclesiastical structures, and but little appears in the homes of the people. We follow the northeasterly shores of the Great Salt Lake for many miles, look out on its sparkling waters and inwardly long to plunge in and free ourselves from the soot and dust of the day's journey. Ogden is passed with a brief stop, and we enter the desert of Northwestern Utah and awaken on the 27th in a similar desert in Nevada. Nor do we find much that is not desert in crossing the whole state on the line of the Central Pacific Ry. We are told the entire state has a population of not more than 50,000, and that it is decreasing in the number of its inhabitants.

That the soil is not unproductive, however, is demonstrated at Humboldt, a station on the railway where water is had for irrigation and which is a veritable oasis in a dreadful desert. A story is related of an enthusiastic native who, in extolling the advantages of his state to an Eastern man, declared that all they needed was plenty of water and good society. His companion replied he had heard that is all that is lacking in hell!

At Humboldt the first Indians were seen—two Piute squaws—one in brilliant paint. The photographic fiends of the party went into ecstasies at once, though it was difficult to get even satisfactory snap-shots owing to the aversion of the Indians to being photographed. They have learned the tricks of the Kodak and other wiles of the amateur photographer. However, at stations further on, by strategy and a liberal use of coin of the realm, a number of quite satisfactory likenesses of some squaws and their papooses were obtained.

Breakfast and dinner were taken on the dining car. At noon we were met by Mr. W. G. Curtis, Assistant to the General Manager of the Pacific System of the Southern Pacific Co.; Geo. E. Gray and Col. Geo. H. Mendell, Corps of Engineers, U. S. A., and other members of the Local Reception Committee who had come out in a private car to meet and welcome us.

From the moment of their arrival the local committee were most assiduous in their attentions to their guests, and until we parted from them at Ashland, Ore., on July 5, they never ceased their ministry to our comfort and enjoyment. The first intimation of their hospitable attentions appeared immediately after their arrival when a number of crates of the most delicious strawberries, apricots and peaches were distributed through the cars with the "compliments of the local committee."

The state line is crossed, and we enter California about 2 p. m. The Truckee River, which we are following, soon leads into the mountains, and after pausing a few minutes at Truckee we are soon among the snow-capped Sierras, and are again enchanted with beautiful mountain scenery. As we slowly ascend toward the summit of the range magnificent views greet us at every turn until we are engulfed in snow sheds and ride mile after mile in a sort of nightmare vainly hoping in a few minutes to come out into the open and get full views of what we are sure, from the tantalizing glimpses we get through the cracks between the boards, must be grand and beautiful scenery. But we hope in vain, for not until we have reeled off some 42 miles of darkness do we emerge from the sheds into daylight again, and then we have passed far down from the summit. The necessity for these snow sheds was very evident, as we could still see snow banks outside as high as the car windows.

A series of small mishaps had occurred to the train. Between Denver and Sacramento three draw-bars were broken. Each occasioned delay for repairs, so Oakland was reached about four hours behind time; further delay occurred at the ferry, and the party did not finally reach the Palace Hotel in San Francisco until about 3 a. m., June 29.

The sessions of the convention began at 10 a. m., on the 29th.

The following are brief abstracts of the papers presented, all of which were published in full in the May number of society's proceedings:

Flow of Water in Wrought and Cast Iron Pipes from 28 to 42-ins. Diameter.

This paper by Mr. Isaac W. Smith, M. Am. Soc. C. E., dealt with investigations made on the flow of water in the pipe lines, which carry the water from Bull Run River to the city of Portland, Ore. The water supply is taken from the river by means of a canal terminating in a funnel mouth connecting with the 42-in. discharge pipe. The water is conducted to the city through 24 miles of riveted steel pipe and 6 miles of cast-iron pipe. The steel pipe is 42, 35 and 33 ins. diameter, and the cast-iron pipe 32 and 28 ins. diameter, the latter diameter being used for a distance of 2,000 ft. to carry the pipe line under the Willamette River. On March 28, 1895, there were 2,995,000 gallons, by reservoir measurement, turned into reservoir No. 1 in 3.7 hours and 617,000 gallons into other reservoirs, making 3,162,000 gallons in 3.7 hours, or 23,410,000 gallons in 24 hours. The flow by weir was 23,750,000 gallons, or 340,000 more than the reservoir and weir measurements combined. On Jan. 21, 1896, all the water was let out of the reservoir and the full flow from Bull Run River turned in, the time being noted as the water level reached each million gallon mark; time being 61 minutes in seven cases, and 62 minutes in three cases, or 10 hours, 13 mins. for 10,000,000 gallons, equivalent to 23,491,000 gallons in 24 hours. On Feb. 27, 1896, the discharge was 23,500,000 gallons through the riveted pipes and 20,750,000 through the cast-iron pipes.

A Water Power and Compressed Air Transmission Plant for the North Star Mining Co., Grass Valley, Cal.

This paper by Mr. A. D. Foote, M. Am. Soc. C. E., described a plant in which air compressors with cylinders 10 × 24 and 18 × 24 ins. are driven by a Pelton water wheel 18 ft. 6 ins. diameter, making 110 revolutions per minute, the water being taken from a canal and conveyed through 2½ miles of 22-in. riveted iron pipe and 7,070 ft. of 20-in. riveted steel pipe, the head being 775 ft. This plant was described and illustrated in our issue of Dec. 19, 1895.

The Condition of Steel in Bridge Pins.

Mr. A. C. Cunningham, M. Am. Soc. C. E., has made a number of investigations as to the strength and quality of steel pins for bridge work, and finds that when they are tested for quality and not for the purpose of getting them past a specification, it is found that forged pins are better than rolled pins, and that a medium hard steel of about 70,000 lbs. ultimate tensile strength will give better results than a soft steel. The tests (a number of which are given in tabular form) show that bridge pins, even when made from a special quality of steel, are not in a uniform condition; the interior portions show a lack of work, and may show excessive segregation, which in steel of common quality is liable to reach a dangerous amount. It is also shown that pins are improved by annealing. The following specification is submitted as being likely to procure as good bridge pins as can be had in common practice:

> Bridge pins shall be made of open-hearth steel. If made of acid steel, the cast analysis shall show not more than 0.06% of phosphorus, nor more than 0.03% of sulphur. If made of basic steel the cast analysis shall show not more than 0.03% of phosphorus, nor more than 0.03% of sulphur. The manganese for either steel shall be not less than 0.5% nor more than 0.8%.
>
> The smallest diameter of the final bloom or ingot to be made into pins shall be at least 50% greater than the diameter of the pin.
>
> All pins shall be stamped with the cast number of the steel from which they are made and shall be stamped with consecutive numbers from the bottom of the ingot to the top.
>
> After pins have been manufactured to diameter, they shall be slowly and uniformly heated to a dark red heat in a suitable furnace, and left to cool slowly for a period of not less than 24 hours. Test pieces cut from near the surface of annealed pins, and of a sectional area of not less than ½ sq. in. shall have an ultimate strength of not less than 60,000, nor more than 70,000 lbs., per sq. in., an elastic limit of not less than half the ultimate strength, an elongation in 8 ins. of not less than 20%, and a reduction of area at fracture of not less than 40%. Test pieces cut from near the center of pins shall comply with the above requirements, except that a fall of 5,000 lbs. in ultimate strength, and a fall of 5% in reduction of area will be allowed.
>
> The fracture of all pin tests shall be free from granulation.
>
> ....
>
> Analyses of drillings taken from near the surface of pins shall not exceed the limits of the cast analysis by more than 10%, and, when taken from near the center, shall not exceed said limits by more than 50%.
>
> Tests and analyses shall be made on such pins as the engineer shall designate.

The Construction of a Light Mountain Railway in the Republic of Colombia.

The railway in question was built for the Caribbean Manganese Co., of Baltimore, Md., and extends from the harbor of Nombre de Dios to the manganese mines, the main line now in operation being about nine miles long. The author of the paper, Mr. E. J. Chibas, Assoc. M. Am. Soc. C. E., was the engineer. The surveys and location were made with difficulty owing to the dense forest and undergrowth, and the absence of paths or roads. During about six months suspension of work, luxuriant vegetation, 5 to 7 ft. high, covered the right of way, which had been cleared and grubbed, and some of the centre stakes were growing into trees. The bridge work gave considerable trouble, the native carpenters being unable to work from plans, and being such poor workmen that they had to be watched to keep them from spoiling the timber when the whole work had been laid out for them. The embankments were only 7 to 8 ft. wide on top, the idea being to widen them with refuse from the mines during operation, but the author did not consider a less width than 10 ft. advisable for a line of 3 ft. gage. The cuts are 10 ft. wide, but 12 ft. would have been better. In pick and shovel work, and in nearly all manual labor, Jamaica negroes proved superior to the natives. The track is laid with 35 lb. rails on 2,200 ties per mile, the ties being usually 6 × 6 or 5 × 6 ins., 6 ft. long. The ballast is a decomposed rock obtained from the cuts. The curvature of the line aggregates about 30% of the total length. The cost of building and equipping 10½ miles of line averaged $13,400 per mile. The average for the Nombre de Dios branch (including wharf, buildings and port terminals) was $6,800 per mile.

Improving the Entrance to a Bar Harbor by a Single Jetty.

In this paper, Capt. T. W. Symons, M. Am. Soc. C. E., U. S. Engineer Corps, describes a plan prepared for the improvement of the entrance to Gray's Harbor, Wash., by means of a single jetty. this plan being applicable here on account of the relations of the currents, tides, volume of flowing water, and other conditions. In general two parallel or converging jetties are used, or one jetty with the other replaced by a headland or permanent shore, but the author believes, from his experience on the Pacific coast, that there are places where double jetties are unnecessary. Such a plan has been successfully carried out at Coos Bay, Ore., and the plan proposed for Gray's Harbor is based largely upon the results obtained and studies made at Coos Bay. The jetty, as proposed, is to be of rubble stone or a brush mattress foundation, the jetty reaching up to the level of high tide, and its total length (to the crest of the bar) being 25,500 ft. The cost of the wall is estimated at $1,000,000, as compared with $2,500,000 for a plan involving two jetties.

Interesting discussions followed the reading of these papers, especially that by Mr. Cunningham.

In the evening a reception was given at the hotel which was largely attended by distinguished citizens of the city and vicinity, and many pleasant acquaintances were made.

On Tuesday, the 30th, the local committee tendered the party an excursion in a steamer on the bay and to the

Union Iron Works. The harbor and Golden Gate were seen to advantage. Luncheon was served on board the steamer, after which appropriate speeches were made. An inspection of the new U. S. battleship "Oregon," now under construction, and of the Union Iron Works completed the day's sightseeing and pleasures. In the evening President Clarke's address (Eng. News, July 2) was read by the Secretary, Mr. Charles Warren Hunt, Mr. Clarke not being present. This closed the formal labors of the convention, and the visiting members and friends committed themselves unreservedly to the hands of the local committee, and for the remainder of the stay in California "joy was unconfined."

The following day the party visited Mayor Sutro's beautiful residence and park, dined at the Cliff House, where hospitality flowed so freely that guests who had never spoken before made speeches and afterwards saw sea serpents or rather seals on the rocks in the bay.

The freedom of the city was conferred upon the visitors. They were invited to the Board of Trade; the Bohemian Club opened wide its doors; everywhere hospitalities were lavished and people "fell over each other" in their efforts to do honor and afford pleasure to the American Society of Civil Engineers.

On July 2, by courtesy of the local committee, an excursion, to which a large number of resident citizens were invited, started by special train to visit the Spring Valley Water-works, Leland Stanford, Jr, University, and Monterey. At San Mateo a large number of conveyances met the train and the party drove several miles throughout a pleasant country to the famous dam of the Spring Valley Water Co., about which so much has been said and written that it has become very familiar to the engineering profession. A thorough examination of the structure was made, and full explanations of the details of construction, were given by Mr. Herman Schussler, Chief Engineer of the Spring Valley Water Co. Then the drive along the lake was resumed until a pleasant grove was reached, where on long tables under the trees a feast was spread with everything pleasant to eat and drink in great abundance. Liquids—not all of which originated in the lake—flowed redundantly and good cheer prevailed. After the feast a very rich program of after-dinner speeches was served, by men of all professions and occupations, from bishop to banker.

Again the carriages were taken and the party boarded the train at San Mateo, full of gratitude to the Spring Valley Water Co. for the delightful carriage ride and dinner. From San Mateo the train sped through one of the garden spots of California—a great grain and fruit-growing belt, through thousands of acres of wheat white for the harvest, where machines operated by 28 horses thresh the grain as it is cut and drop it off in bags, through beautiful parks of live oak, through miles of fruit orchards, apples, peaches, apricots, prunes and cherries, through hundreds of acres of seed onions and sweet peas—everything is on a most generous scale in this country.

We stopped a few minutes at Palo Alto, got a glimpse of the grounds and buildings of the Leland Stanford, Jr., University, and then hastened onward through San Jose where we could see upon Mt. Hamilton, 28 miles to the eastward, a white speck that indicates the location of Lick Observatory, with its world-renowned telescope. At last we approach Monterey and are soon at the Hotel Del Monte. In the evening, as we view the hotel and park, it seems a veritable fairy land, an impression which the light of the following day fully justifies, for the place is lovely almost beyond conception. Nature and man have co-operated in perfect union and harmony in the creation of the Del Monte. Nature laid the foundation, planted the great oaks and cypresses, and man erected the beautiful hotel and cultivated and adorned the park with consummate taste, harmony and skill. All the flowers that will thrive in the congenial soil of Central California here unfold in exuberant bloom; strange, fantastic, semi-tropical plants exhibit their foliage in the Arizona Garden; tempting vistas with paths leading in every direction invite to strolls in the park. Of all the places visited during the trip none approaches Del Monte for loveliness.

Time and space fail to give in detail a proper description of the delightful drive of 18 miles on the 3d of July through the quaint old town of Monterey, located irregularly on the Bay of Monterey—through Pacific Grove, the Chatauqua of the Pacific coast, on through an immense natural park to the ocean, along the ocean to Cypress Point, with its fantastic forest of hoary wind-swept cypress trees, reputed to be as ancient as the cedars of Lebanon—on back to Monterey, and the Hotel Del Monte, and dinner; after which the train is again taken, and the return journey made to San Francisco, via, Santa Cruz and over the Santa Cruz Mountains, passing a grove of "big trees," some of the smallest of their kind, but one of which ("Fremont's tree") still standing and growing, easily accommodated 34 of the party with room to spare in its hollow interior.

According to the program, the time had arrived to leave California, but our hospitable hosts importuned us to stay another day, as they would not be satisfied without showing us something further of the material development of their wonderful state.

Yielding to their solicitations, another night was spent in San Francisco, and on the morrow, July 4, under escort of the local committee the party was taken to Sacramento and thence to Folsom, to examine the electric power plant located on the American River at that place, and illustrated and described in Engineering News of April 11, 1895, and May 7, 1896.

The electric current is transmitted from Folsom to Sacramento, 22 miles, and furnishes the motive power for all the electric street car lines in the city. The shops of the Southern Pacific Ry. are also supplied with electric power and experiments are being made to determine whether it will be sufficiently economical to warrant extending the use of the electric power to all the shop uses.

It is to be noted that a difficult engineering problem seems to have been satisfactorily solved in this water-power plant. It has been found that in diverting the water from rapid silt-bearing rivers like the American, very great difficulty has been encountered in keeping the comparatively slow flowing canals from becoming filled by deposits of silt. This difficulty is overcome at the Folsom dam by what is virtually a large settling basin, in the bottom of which are outlets, passages and gates, through which the sediment is washed into the river below the dam at intervals and only the water freed from its burden of silt is allowed to pass through the headgates into the canal. The gates are controlled and operated by hydraulic jacks and are very easily handled.

Near the dam is located the state prison, to which a brief visit was made, and the remainder of the afternoon was spent in Sacramento, where points of interest were visited the state capital with its very beautiful park, the historical Sutter's Fort and other places. The "glorious Fourth" was celebrated by the natives with characteristic Western energy and vim. To the ladies of the party who had not satisfied themselves with curios in Chinatown at San Francisco, another opportunity was presented in the Japanese bazaars of Sacramento, which were the only shops open on the Fourth.

About 9 in the evening a start was made toward the North, and on awakening the following morning the train was keeping company with the Sacramento River, which as it comes from the mountains is a clear, sparkling stream easily forded. We stopped at Craig, a resort in the mountains, with an outlook on Mt. Shasta, a wonderful peak, rising 14,442 ft., covered with a beautiful mantle of perpetual snow. We pass Castle Gate and are apparently lost in the mountains. Moss Brae Falls are seen, a series of dainty cascades, springing out from a drapery of verdant moss and foliage, and leaping and bounding down the steep mountain side to the valley below. Not far beyond we come to the famous Shasta mineral springs. After slaking our thirst with the cool, pungent water, the journey was renewed, penetrating further into the mountains and rising by loops and turns to the summit of the divide between the waters of the Sacramento and the Umpqua rivers, and as we rise we gain ever new views of beautiful Mt. Shasta, traveling nearly all day in sight of it.

About 4 p. m., our friends of the local committee, Mr. Curtis and Colonel Gray, who had accompanied us beyond the state line of California, parted from us at Ashland, Ore.

Too much praise cannot be given to our fellow members of the American Society of Civil Engineers on the Pacific coast and their friends for the magnificent hospitality which they extended to their visiting guests. From San Francisco to Tacoma attentions were showered upon the visitors and nothing was left undone that could add to their comfort or pleasure. The local committee of San Francisco, headed by their chairman, Mr. Curtis, were particularly assiduous and successful in their efforts to render the convention memorable by the heartiness of their welcome, and the wealth of good things prepared for their guests.

The remainder of the journey to Portland was pleasantly passed. The railway runs through some treacherous country, where slides occur, at one point the portal of a tunnel was once closed by a slide, and at another three miles of the road were buried under an avalanche of earth and debris which dropped from the mountain side, creating a temporary dam which formed a lake some miles in extent. This was speedily emptied when the dam gave way soon after the water began to pass its crest.

Portland was reached early on July 6. After breakfast at "The Portland" the party was conducted about the city and to Portland Heights, from which magnificent views of the surrounding country were had. the three great mountain peaks, St. Helens, Adams and Hood, like stars of the first magnitude, claim special attention, standing separate and apart, each mantled with perpetual snow.

Our Portland friends had arranged a trip by train to the Cascades and Locks, about 50 miles up the Columbia River. Here more beautiful scenery was enjoyed, the Locks were inspected, lunch was taken, and a salmon wheel was visited. The wheel is propelled by the current, and carries large buckets or scoops, which gather all the fish within their reach and deposit them on a platform.

But few of the party from the East had any conception of the abundance of fish or the size to which they attain in these Western rivers; and the sight of 50-lb. fish as they came flopping from the wheel was a revelation. It seems, however, a barbarous way of fishing and is prohibited by law by our Canadian neighbors.

Returning to Portland, the journey north was resumed, and Tacoma was reached late in the evening.

Here, as elsewhere, we were royally received, and were escorted about the town to view its sights.

In the afternoon the party were taken on an excursion to Point Defiance, and by steamer on the bay. In the evening an informal reception was held at the Tacoma. after which the party began disintegrating, a number leaving for the Yellowstone Park. Those remaining started northward again in the morning, July 8, by steamer, touching at Seattle and Port Townsend, and stopping at Victoria for a few hours for supper and a trip through the town.

Morning found us at Vancouver, which is a thriving city and an important port.

From here the journey east over the Canadian Pacific Ry. was begun. The water in the rivers was very high,. thousands of acres were flooded on either side the railway. As the afternoon wore away, however, the submerged plains were left behind and we were again enjoying picturesque scenery in the Fraser Canon which was followed until daylight faded into darkness.

The morning of the 10th found the party in the Lake region, circling the shores of the great Lake Shuswap, which the railway follows for 50 miles. The Lake is hemmed in by mountains rising high on every side and covered with virgin forest.

The country is said to bear a strong resemblance to the lake country of Scotland. It is a paradise for sportsmen, the forests abounding in large game and the lakes in fish and water fowl.

Leaving the Lake country the descent is made to the westerly crossing of the Columbia River at Revelstoke, the railway runs in an easterly direction up the Canon of the Illecilliwaet, leaving the Columbia, which makes a long detour to the north sweeping around the Selkirk Mountains. South of Revelstoke it widens into the Anow Lakes.

The Illecilliwaet is a torrential mountain stream fed by the melting snows seen on all sides on the summits of the lofty mountains of the Selkirk range. Recent hot weather had swollen all the streams, making the waters turbulent and muddy; the valleys were flooded, the rails of the railway being at times covered to the depth of 6 to 12 ins. A trestle on the line was started from its foundation and the train was stalled at a small station in the mountains in company with another train which had already been waiting for 24 hours.

A weary wait with frantic efforts to get into communication with the railway officials, who were empowered to advance the train and transfer the party to Glacier, an interesting and comfortable station to spend the waiting hours, failed to meet with success. Dinner and supper were taken on the dining car, and one by one the party retired for the night.

At midnight the road was opened, and the party was joined by Chief Engineer P. Alex. Peterson, M. Am. Soc. C. E., who had been superintending the repairs at the trestle, and the train moved forward up the canon, rising from the bottom of the valley and climbing the sides of the mountains on narrow shelves. The scenery grew wilder and the sleeping members of the party were dragged from their berths and began to appear variously clad in all sorts of garments, from linen suits worn the previous day, during the heat in the valley, to overcoats and blankets. But they were amply repaid for the loss of slumber and a hasty toilet. Stupendous mountains, towering on every side, began to appear, at that early hour in this northern latitude—day began to dawn at 2 a. m. Higher and higher the train climbed up the mountain side, around a "loop" most skilfully located in terraces, almost vertically above each other, until the altitude attained brought us in friendly proximity with the summits of the great peaks all around us, Ross, Cheops and Dix Donald being the most conspicuous. The little river was seen far down in the V-shaped canon, the trestle recently repaired was crossed, and when a turn of the road brought the great Glacier plainly into view, high up on the side of Ross' Peak, daylight had so far advanced that the billows of ice were plainly visible, extending upward toward the clouds in the stupendous masses—great plains of frozen crystal, hundreds of feet in depth.

Other glaciers were seen in the vicinity, but none of such extent or beauty. For many miles up to and through Roger's Pass, the scenery is sublime beyond the power of pen to describe.

Time and space fail to record the interesting features of the descent to the easterly crossing of the Columbia, at Donald, the ascent of the Kicking Horse Pass to the Continental Divide, in the heart of the Rocky Mountains, or the brief stop at Banff, in the Canadian National Park.

At Banff another division of the party took place, and the practical breaking up of "Tour No. 1." Those who were fortunate enough to go on "No. 4" are probably at this writing still enjoying the delights of the Yellowstone Park, but even those who came directly east from Banff have had sufficient grand scenery to last them at least another year.

The convention, as a pleasure excursion, at least, was an unqualified success, and I believe will have no small influence in strengthening the fraternal bonds between the members of the East and the Far West, as well as increase the interest of the engineers of the Pacific Slope in the American Society of Civil Engineers.

PLANS FOR RAILWAY TRACK DEPRESSION on Atlantic Ave., Brooklyn, were submitted to the commission in charge of that work by the counsel of the Long Island R. R. Co., on July 27. It is proposed to lower the tracks from the Flatbush Ave. terminus to the city limits, a distance of 31,040 ft., and carry the streets across the sunken tracks by 38 bridges 60 ft. wide at important streets and 46 foot bridges 14 ft. wide at other streets. The estimates for the work are as follows:

For excavating and wasting, 50 cts. per cu. yd.
For masonry in walls, $8 per cu. yd.
For concrete, $6 per cu. yd.
For first-class masonry, $13 per cu. yd.
For steel construction, 4 cts. per lb.

The consulting engineer estimates that to carry out the entire work, as shown on plans submitted and sketched out in this report will cost $3,912,932.

The above estimates does not include engineering expenses, the cost of removing water mains, alterations to sewers and other work connected with the city works department, or the cost of maintaining the railroad traffic during construction.

◆

THE COMPETITIVE DESIGNS for the proposed drawbridge over Newtown Creek, Brooklyn, N. Y., were opened on July 23. According to the Brooklyn "Eagle," those submitting designs were the following:

Name.	Type of bridge.	Estimated cost bridge.	Price, design.
E. B. Jennings	Bascule.	....	$1,000
W. H. Breithaupt	Hinged arch.	$200,000	6,000
Chas. E. Bedell	Bascule.	....	1,600
John D. Wilkins	....	....	6,300
Chas. A. Steiner	....	....	500
Waddell Bridge Co.	Lift.	....	...
Thos. E. Brown, Jr.	Bascule.	100,000	5%*
Alfred Liebmann	Lift.	....	500
Structural Eng. Co.	Lift.	400,000	2%*
Scherzer Bridge Co.	Rolling lift.	....	...

*Of cost.

◆

THE EAST RIVER TUNNEL proposed by Benj. S. Hening and his associates is likely to become a reality at an early date, if a long article in the "Tribune" of July 26 may be believed. The tunnel is to extend from a New York terminus at Park Row and Ann St., to a point near Willoughby Ave., in Brooklyn, a distance of about 8,700 ft., of which 2,600 ft. would be under the river. The section proposed is a horseshoe 28 ft. in width and 24 ft. in height. A franchise was granted for the tunnel by the New York Board of Aldermen some weeks ago, and it is stated that the funds for the work have been raised by an auxiliary organization known as the Columbian Co.

◆

A NEW EAST RIVER BRIDGE, to parallel the present structure and to be built solely for the use of the elevated and surface railway lines, has been proposed by President Jas. Howell, as an offset to the petition to permit elevated railway trains to run across the present structure. It would seem highly unwise to build another bridge close beside the present one until the traffic capacity of the present is fully utilized and until it is ascertained what relief will be given by the completion of the new bridge at Grand St. As New York and Brooklyn are not likely to supply funds for such a bridge, and private capital is still less likely to take it up, the newspaper discussion spent upon it is probably wasted.

◆

WORK ON THE HUDSON RIVER TUNNEL may be resumed, if the plan for the reorganization of the company agreed upon at a meeting of the bondholders in London last month is successful. It is stated that Mr. Chas. M. Jacobs has presented an estimate setting $2,376,779 as the cost of completing the tunnel and its approaches, and purchasing land for its terminals. By the reorganization it is hoped to raise sufficient additional funds to complete the work. It will be remembered that one tunnel has already been driven nearly across the river.

◆

THE NEW YORK RAPID TRANSIT LAW was declared constitutional by a majority of the Appellate Division of the New York Supreme Court on July 28. Two of the five judges dissented from the opinion. While this decision does not remove the obstacle presented by the refusal of this same tribunal some months ago to approve the plan prepared by the Rapid Transit Commission, it appears to open the way for the preparation of some plan involving smaller first cost, which could again be presented to the authorities for approval.

◆

THE CONTROL OF STREET CAR FARES by the state railway commission is to be tested in California. The commission will investigate the cost, debt, expenses, and earnings of the roads, and in case information is refused by the companies will carry the matter to the courts.

◆

A FIVE-CENT FARE for all suburban distances under 20 miles has been adopted by the Chicago & Northern Pacific Ry., running out of Chicago. This is said to be the cheapest suburban transportation ever offered by a railway company in this country.

◆

ELEVATOR CHARGES are complained of in a communication sent by a committee of canal carriers to the New York Produce Exchange. It is shown that for transferring a boat load of 8,000 bushels of wheat from Buffalo to New York the boatman has to pay $104 at Buffalo for the transfer, trimming, storage, etc., and $143 at New York. He receives a gross freight of 3¾ cts. per bushel, and after deducting the transfer charges as above, the insurance and the towing, has $113.50 left to feed his teams and crew, pay his men and bear other expenses of his journey of 1,000 miles, for west-bound freight is not often obtainable, and when it can be secured barely pays for the time of detention necessary to secure it. The protest continues as follows:

> It is adding insult to injury for the grain elevator combines, as aforesaid, to tax the state canal traffic upwards of $100 more on a boat load of oats than we, the canal carriers, receive gross for carrying it such a long distance from Lake Erie to New York Harbor, when it is taken into consideration that the entire time consumed for the simple transfer of grain at Buffalo and New York does not exceed 1½ hours at each port. It is no uncommon occurrence for the modern elevators at Buffalo and New York to transfer a boat load of grain from lake vessel to canal boat and from canal boat to ocean ship complete in the short space of 50 minutes.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred near Murphysborough, Ill., July 21, on the Chicago & Texas R. R. A trestle failed, precipitating the rear car of a passenger train to the ground. Fifteen passengers were injured. Cable dispatches from Bombay, India, state that on July 27 a passenger train was derailed on the railway between Bombay and Delhi and 50 passengers were killed.

◆

A BOILER EXPLOSION occurred at English, Ind., July 20. The regular engineer was absent. The substitute in charge was killed.

◆

A PISTON ROD BROKE on the steamer "Connecticut," July 23, of the Providence Line, on Long Island Sound. The broken rod connected with a low pressure cylinder and had been inspected by the chief engineer only three minutes before. The accident occurred at midnight and on a quiet sea, and steam was shut off before any damage was done to the vessel.

◆

A WATER-WORKS RESERVOIR is reported as having failed at Stanford, Ky., July 17, flooding a part of the city and doing some slight damage.

◆

AN ARTESIAN-WELL FRAUD is reported from Washington, D. C., the U. S. government being the victim. In 1893 a contract was let for a well to supply Fort Meyer, near Washington, the well to have a capacity of at least 50,000 gallons a day. Rock being struck in this well by a sub-contractor at some depth, a second well was started in 1894. Water was developed at a point surprisingly near the surface, but after the first test the contractor claimed that the well had been tampered with. The authorities not being satisfied with the well, anyway, a third one was put down in 1895. Water was again found near the surface. It was of a satisfactory chemical character, but the objection was raised that the well was not deep enough to insure a permanent supply, and on a test it yielded only 48,000 gallons a day. The contractor said he would sink the well deeepr, and shortly afterwards made a test which showed a yield of 60,000 gallons. The well was accepted and the contract price, $8,000, was paid in November. The well was not put in use until this year, when it was found to give little or no water. The Cook Well Co., of St. Louis, was called on to investigate the matter. It was found that both the second and third wells had been connected by means of a pipe with a near-by brook. A second pipe was laid to the third well to increase the apparent yield from 48,000 to 60,000 gallons. It is claimed that a dam was thrown across the stream and that the water pumped from the wells during the test was carefully conveyed back to the stream, the latter having only a small flow. We cannot vouch for the accuracy of the details of the above story, as they are taken from a press dispatch, but there is no doubt regarding the attempted fraud and its general method.

◆

THREE PUMPING ENGINES OF 12,000,000 GALlons capacity each are to be purchased for the Chicago, Ill., water-works. Plans and specifications for these pumps are now being prepared and it is stated that bids will be called for within a few weeks. One pump will be placed at the Lake View Station, one at the Fourteenth St. Station and one at the Chicago Ave. Station. The work will include all the necessary boilers and appurtenances.

◆

A WATER-POWER FRANCHISE is under consideration at Sault Ste. Marie, Mich. The proposed ordinance grants a franchise to Messrs. Edw. V. Douglass, of Philadelphia, and Francis H. Clergue, of New York, for building and operating a canal 15 ft. deep and not less than 150 nor more than 600 ft. wide through the city, from a point on the shore of St. Mary's River above the St. Mary's Falls Ship Canal. The city is given the right to discharge surface water and sewage into the canal, but must pay $4,000 a year for 20 years and construct such bridges over the canal as may be necessary. The proposed franchise also provides that the city shall pay $6,000 a year for 20 years for 400-HP., including a site to make use of it. No provisions regarding charges for power supplied to manufacturers are included in the franchise.

◆

FASTER TRAIN SCHEDULES are to be put into effect on the Manhattan Elevated Ry. on Aug. 3. A reduction of three minutes will be made in the schedule time between terminals on the Second, Third and Sixth Ave. lines. The following table summarizes the facts of interest:

Line.	Length miles.	No. stops.	Present schedule time* mins.
Second Ave	8.76	25	43½
Third Ave	8.48	25	43
Sixth Ave	10.76	27	52

*By Official Guide.

Newspaper reports give the present schedule time something less than the above.

◆

AMERICAN FILES are being sold in England in competition with those of Sheffield manufacture. "The Engineer" (London) in its issue of July 17 says:

> Mr. J. W. Schofield, a Sheffield manufacturer, has directed the attention of Sir Howard Vincent, M. P., to the severe American competition to which Sheffield file manufacturers are now subjected by their American rivals in the English markets. "My agent," he says, "writes me this morning that a large order, for which we quoted an outside discount, has gone to America at 67½% and 5%, and this, with freight and charges, represents approximately 70% off Sheffield list, which will mean a heavy loss if supplied by Sheffield manufacturers." Mr. Schofield adds that surely the time has come when something should be done in the way of practically testing protection by the imposition of a duty on goods, which can be seriously affected by combination on this side. He suggests in that connection agricultural machinery and files—each of them small matters in themselves, but of vast importance to those in this country engaged in their production. Sir Howard Vincent, in his reply, says that he is painfully aware of the existence of this state of affairs, and has for years past done his best to remedy it, but expresses his sorrow at having been almost single-handed in the matter, and at receiving so little support from any quarter.

◆

A STEAMSHIP LINE from Japan to Seattle, Wash., in connection with the Great Northern Ry., is announced as arranged for. At the beginning there will be one steamer a month each way. The Royal Japanese Mail Steamship Co. is said to be the company which will undertake the venture.

◆

A NEW METHOD OF MARINE PROPULSION is to be tested by a naval board this fall. The system consists, according to newspaper reports, of an apparatus for exploding a mixture of gas and air, as in an ordinary gas engine, and directing the explosive force directly against the water at the stern of the boat without the intervention of any pistons, screw propellers or other machinery. The system is the invention of John A. Secor, who is building a 75-ft. launch to be fitted with this system at the foot of 44th St., New York city.

THE WEST SIDE IRRIGATION AND MINING CANAL IN WYOMING AND COLORADO.

By Elwood Mead, M. Am. Soc. C. E.

(With inset.)

About 70 miles south of Rawlins, Wyo., in Routt county, Colo., is an area of gold-bearing sand which promises to attract much attention in the near future. Beginning at the southern boundary of Wyoming, it extends south to the divide between Bear and Snake rivers, and from Range 89 to Range 97 west, embracing in all a district about 30 miles wide and 50 miles long. This deposit of placer gold has apparently no relation to existing water courses nor to any definite source of supply, but wherever bars or areas of sandy soil occur, there gold in paying quantities is usually found. In a series of tests which embraced over 20,000 acres, the average value of the ground tested was over 30 cts. per cu. yd. and the returns from the hydraulic operations in this district last season, as far as received, have shown results equally large.

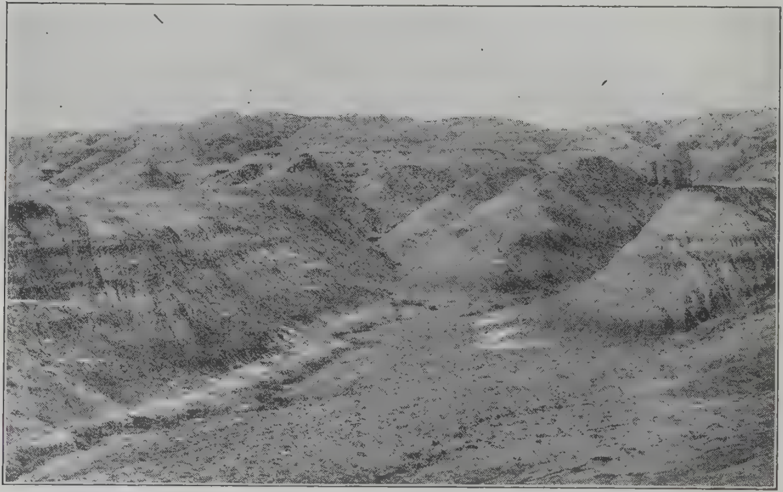

Fig. 4.—Character of Country Through Which Canal must Have Passed Had Not Pipe Line Been Adopted.

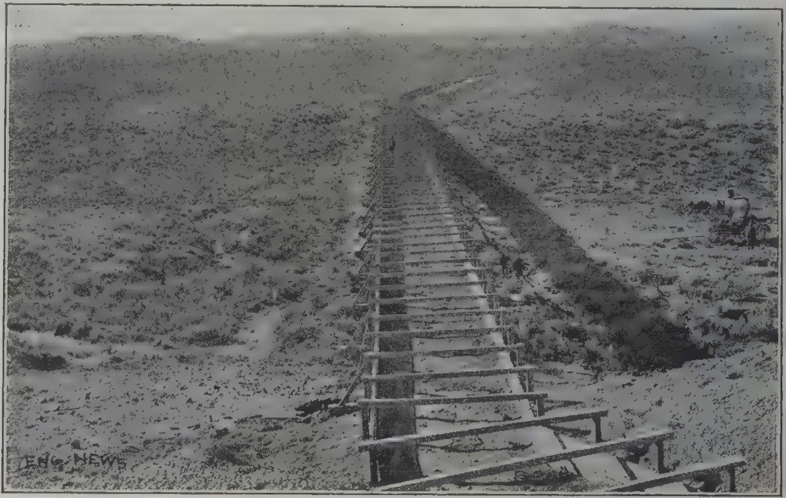

Fig. 8.—View of Flume With Mountains in the Distance.

VIEWS ON THE WEST SIDE CANAL IN WYOMING AND COLORADO.

The largest work yet constructed for washing and securing this gold is the West Side Canal, owned by the West Side Mining Association, composed principally of citizens of Providence, R. I. This association has secured, by location and purchase, several thousand acres of placer ground lying south and east of Snake River in the northwest corner of the district. To secure the required elevation for their water supply it was necessary to build a canal about 29 miles long, starting at Dixon, Wyo., and terminating on the south side of Dry Gulch on one of the largest and richest bars owned by the association. The location of the canal is shown by Fig. 1 and the head gate by Fig. 2. This work was begun in July and completed in November, 1895. Mr. Edw. A. Greene, M. Am. Soc. C. E., was the contractor, and the writer was chief engineer. Messrs. F. J. Cramer and Fred Bond were engineers in charge of the first and second divisions, respectively, of the canal. Messrs. W. B. Haskins, Geo. E. Perkins and Wm. Howard were trustees of the association. The canal is intended to supply water for the irrigation of about 5,000 acres of farming land and to deliver 1,500 miners' inches of water on the bar at the lower end. At the head it is 10 ft. wide on the bottom and 16 ft. wide on the water line. The lower bank is 4 ft. high, and the canal is intended to carry 3 ft. of water with a grade of 4½ ft. per mile. Ten miles from the head the width on the bottom is reduced to 8 ft. and the grade is 2½ ft. per mile. Two cross sections of the canal are shown by Fig. 3.

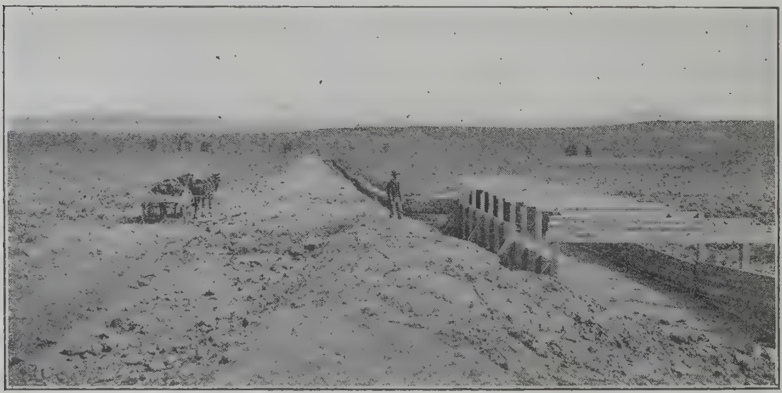

Fig. 5.—Change From Pipe Line to Canal.

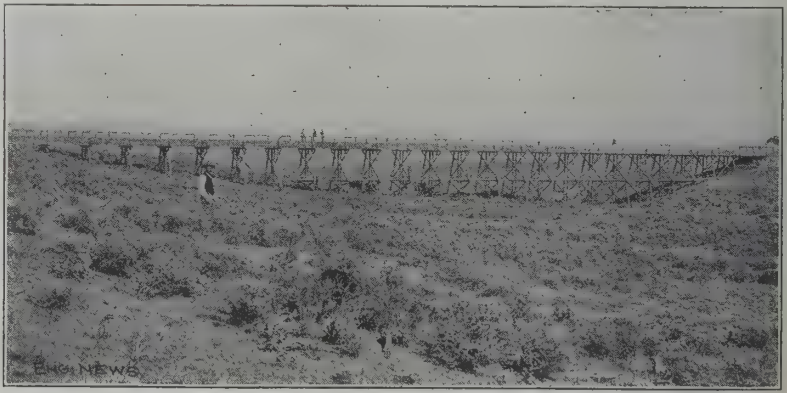

Fig. 9 —View of Flume Across Small Gulch.

STRUCTURES ON THE WEST SIDE CANAL.

The most interesting feature on this canal is the extent to which wooden pipe has been utilized. As the ditch runs almost parallel to the stream and through a broken country, to have crossed the various drainage channels with a grade canal would have greatly increased its length, besides requiring the erection of several long and high flumes. This was given up and instead pipe lines following the irregularities of the surface were substituted in the most difficult locations. The first of these is at the crossing of Four Mile Creek. To follow a grade line up this creek to a point where it could be flumed would have required nearly ten miles of ditch and two flumes about 1,200 ft. long, while an inverted syphon crossing directly from the east to the west side of the valley would be only 6,500 ft. long, and this was substituted. This pipe has an internal diameter of 3 ft., a total fall of 24½ ft., and a maximum static head at the creek crossing of 90 ft.

Five miles below the outlet of this pipe the canal grade passed along the slope of a series of bad land hills which border the river. The slope of these hills is so precipitous and their outline so broken that the construction of a grade canal was out of the question, even if the soil had been of a satisfactory nature, but in addition to the other obstacles the large percentage of gypsum and sodium salts which it contains caused it to dissolve almost as readily as sugar when exposed to water. It was decided, therefore, to carry the water around these hills by means of a pipe line laid in the river valley, at their base. This pipe is about 9,000 ft. long, and from where it drops into the valley at the upper end to where it rises at the lower is from 50 to 80 ft. below grade. Aside from its being the only satisfactory means of passing this obstacle, it is believed to be cheaper than an earth canal owing to the saving in distance. To have followed the contour of the hills would have required a canal about seven miles long, or about four times the length of the pipe. The accompanying view, Fig. 4, shows the character of the country avoided.

A third pipe line crosses Dry Gulch, the static head at the lowest point being 85 ft.

The pipe used is what is known as Allen's patent stave pipe. The staves are made of Texas pine and Oregon fir, shaped from 2 × 6-in strips, varying in length from 12 to 18 ft. and banded with ½-in. iron rods spaced to give a factor of safety of five for the varying static heads.

To secure the maximum discharge, the bottom of the inlet of each pipe is placed 6 ft. below the grade of the ditch. The inlet is expanded, being 4 ft. in diameter at the end and decreasing to that of the pipe in 12 ft. A 4-in. blow-off is placed in the lowest point of each pipe, to drain them when necessary and to permit of the removal of sediment should any accumulate.

The inlet and outlet boxes of all pipes are of timber, as are the head gates, flumes, etc. No masonry was employed. Lumber could be had from the mountains near by and was cheap, while there was no satisfactory stone, lime or cement on the ground, and the distance to the nearest railway, 70 miles, made the cost of outside material prohibitory. The view, Fig. 5, shows one of the changes from pipe line to canal, and details of several of these penstocks are shown by Fig. 6. A view of the mouth of one of the penstocks is shown by Fig. 7. Two flumes are shown by the views, Figs. 8 and 9.

are its durability and the danger from leaks resulting from shrinkage when not in use. Wood-pipe kept constantly filled under the pressures which these must sustain would probably last as long as wrought iron in the alkaline soils of this region. Some have been in use 30 years with no evidence of decay; but this pipe will be emptied in winter, as the climate of this region will not permit operating the canal for from four to five months. If left exposed during this time the life and usefulness of the pipe would probably be brief. To preserve it from decay and to lessen the danger from accidents or malicious injury these pipes have been buried, the trenches in which they were laid being 4 ft. deep. The pressure will, it is believed, force enough water through the pores of the wood to moisten the surrounding earth, and this, taken with the fact that the ground will be frozen during the greater part of the time the pipe is empty, will largely if not entirely prevent both shrinkage and decay during this period.

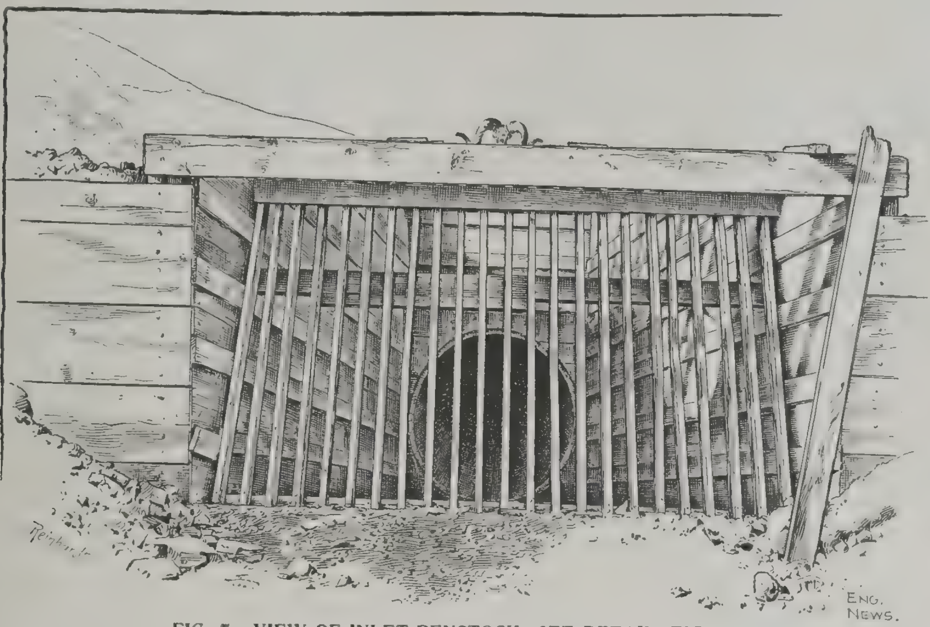

FIG. 7.—VIEW OF INLET PENSTOCK (SEE DETAIL, FIG. 6).

The distribution of gold in this district is somewhat unusual. It is almost as abundant in the roots of the sage brush as on bed rock. There are no nuggets; every particle is of exceeding fineness, from 1,200 to 1,500 being required to make a cent in value. This fact proved for several years an insurmountable obstacle to saving it, as it was carried off with the sand. The first successful washing plant was built two years ago on Four Mile Creek by the Rock Springs Mining Co. The illustration of their device shows its character. Fig. 10 shows it in detail and Fig. 11 is a view of it. It consists of the ordinary sluice box, in the bottom of which is a perforated iron plate, 32 ft. long, the perforations being ⅛ in. in diameter. The mixture of water, gold and fine sand passes through these openings, falling into a tank from which it is distributed in a thin uniform layer over an incline having a fall of 6 ins. in 12 ft. The bottom of this incline is covered with burlap, and as the depth of water and gold bearing sand which flows over it does not exceed ½ in. the gold is caught and held in the meshes of the cloth. No quicksilver is used in either the sluice boxes or the incline. Success in saving the gold depends upon having the soil thoroughly dissolved before it reaches the perforated plate and in having enough water to prevent sand lodging on the burlap.

The West Side Association will use a modificaton of this device, designed by Mr. M. J. Miller, a mining engineer of Chicago. The same method of separating the gold and fine sand from the coarser material will be used, and practically the same plan for distributing the water and gold bearing sand in a thin layer on the incline, but the bottom of this incline instead of being of burlap will consist of a series of indented iron plates which will have the bottoms of the depressions filled with quicksilver.

The canal was completed too late in the season to permit of washing gold last fall, but it was expected that it would be begun about April 1, 1896. Two washing plants will be used, each utilizing 750 ins. of water. This will be distributed by means of wrought iron pipes, connected with a stand-pipe placed at the south end of the Dry Gulch pipe line.

About 300,000 ft. of lumber were used in flumes and in the washing plants. This cost $12 per thousand at the mill and about $27 per thousand when placed in the flumes and other structures. The wood pipe cost $2.25 per ft., laid, with a guarantee of maintenance for eight months. Earth excavation was 8 cts.; loose rock, 27 cts.; solid rock, 60 cts. The canal, independent of the washing plant, cost, complete, $150,000.

The work included 89 acres of plowing, 187,845 cu. yds. of earth excavation, 30,043 cu. yds. loose and 6,442 cu. yds. of solid rock excavation, 114,114 ft. B. M. of fluming and 17,536 of lin. ft. of wood pipe.

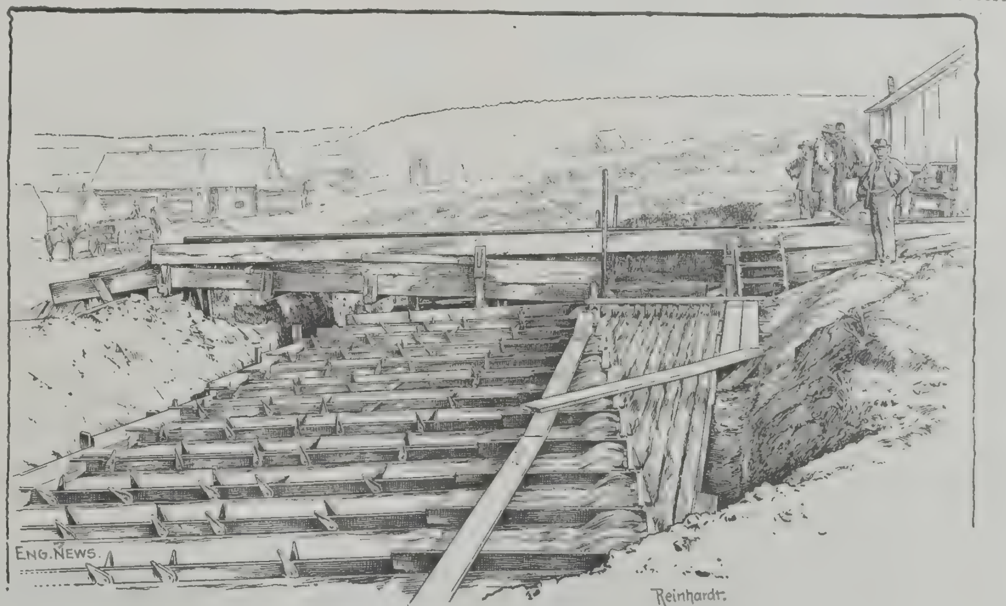

FIG. 11.—VIEW OF GOLD WASHER.

◆

STATISTICS OF RAILWAYS OF THE UNITED STATES FOR THE YEAR ENDING JUNE 30, 1895.

The Statistican of the Interstate Commerce Commission, Prof. Henry C. Adams, has furnished to the press an advance abstract of the forthcoming eighth annual statistical report of the Commission. From it we take the following figures of principal interest to our readers:

> In the introduction of the report reference is made to the effect of the continued business depression, and the large number of receiverships. On June 30, 1895, 169 roads were reported in the hands of receivers, showing a net decrease of 23 during the year. The roads under receivers operated 37,855 miles of line, which shows a decrease of 2,963 as compared with 1894. The railway capital represented by these roads was nearly $2,500,000,000, or about 22% of the total railway capital in the United States.
>
> Mileage.—The total railway mileage in the United States on June 30, 1895, was 180,657 miles, an increase of 1,949 miles, or 1.09% being shown. The increase in 1894 was 2,247 miles, or 1.27%, which was less than for any preceding year during the period for which reports have been made to the Commission. The territory and states in which the increase in mileage exceeds 100 miles are, Arizona, 247 miles; Illinois, 188 miles; Pennsylvania, 157 miles; Maine, 133 miles; Texas, 110 miles, and Montana, 106 miles. The aggregate length of all tracks in the United States on June 30, 1895, was 236,894 miles. Included in this total track mileage were 10,640 miles of second track, 975 miles of third track, 733 miles of fourth track, and 43,888 miles of yard track and sidings.
>
> Classification of Railways.—The number of railway corporations on June 30, 1895, was 1,965, of which 1,013 maintained operating accounts, and 800 financial accounts. During the year 14 roads were abandoned, 9 merged, 32 reorganized, and 28 consolidated. Forty-two companies, each operating more than 1,000 miles, operate 100,715 miles of line, or 55.67% of the total railway mileage; 24 roads, with an operated mileage ranging from 600 to 1,000 miles, operate 18,896 miles, or 10.45%. One hundred and thirty-three roads, or 12.05% of the operating companies operate 145,155 miles, or 80.24% of total mileage in operation.
>
> Equipment.—The increase in number of locomotives in service was 207, the total number on June 30, 1895, being 35,699. Of this number, 9,999 were passenger locomotives, 20,012 were freight locomotives, 5,100 were switching locomotives, and 588 were unclassified. The number of cars of all classes reported, being those owned by railways, was 1,270,561, which indicates a decrease of 7,517 as compared with the previous year. Of the total cars reported, 33,112 were in passenger service, 1,196,119 were in freight service, and the remainder, 41,330, were cars used by the reporting companies in their own service. There was an increase of 94 in the number of passenger cars, and an increase of 1,439 in cars assigned to company's service, but cars in freight service decreased 9,050. The explanation of this decrease is not wholly to be found in an effort on the part of the railway companies to economize in equipment, but rather in the increased use made of private cars.
>
> From the summaries given it appears that there was a decreased efficiency in passenger service, and an increased efficiency in freight service during the year covered by the report. The number of passengers carried per passenger locomotive was 50,747, or 3,907 less than in 1894. The number of passenger miles per passenger locomotive was 1,218,967, or 225,433 less than in 1894, while the number of passenger cars per 1,000,000 passengers carried was 65, or 12 greater than the preceding year. This is probably largely due to decreased travel on account of business depression, but it also suggests that passenger traffic has returned to its normal condition previous to the World's Columbian Exposition. The number of tons of freight carried per freight locomotive in 1895 was 34,817, showing an increase of 2,908 when compared with the corresponding figures for 1894. The number of ton miles per freight locomotive was 4,258,821, the increase over the previous year being 242,066. These figures indicate increased economy in transportation of freight. The same result is shown by the fact that 1,888 freight cars were required to move 1,000,000 tons of freight in 1894, and 1,717 in 1895. These figures, however, are not satisfactory because the basis of the computations does not include cars not owned by railway companies, in which a large proportion of freight is transported.

Out of a total equipment of 1,306,260 locomotives and cars, only 362,498 were fitted with train brakes, and 408,856 with automatic couplers on June 30, 1895. The increase in equipment fitted with train brakes was 31,506, with automatic couplers, 51,235. The summaries presented show that almost all passenger locomotives are fitted with train brakes, and 16,712 out of 20,012 freight locomotives have them. The number of passenger locomotives fitted with automatic couplers on June 30, 1895, was 3,893, the increase during the year being 414. It appears that 6,106 passenger locomotives were without automatic couplers. The number of freight locomotives fitted with automatic couplers was 2,039, the increase during the year being 731. On June 30, 1895, the number of passenger cars in service was 33,112, of which 32,384 were fitted with train brakes, and 31,971 with automatic couplers. The number of freight cars in service was 1,196,119, of which 295,073 were fitted with train brakes, and 366,985 with automatic couplers.

Employees.—The number of men employed by railways shows an increase of 5,426, as compared with last year, the number of employees being 785,034 on June 30, 1895. The returns for the present year show that 128 men were assigned to Maintenance of Way and Structures per 100 miles of line, against 123 in 1894. The number of men correspondingly assigned to Maintenance of Equipment also shows a slight increase, being 88 for 1895, and 86 for 1894.

Capitalization and Valuation of Railway Property.—The amount of railway capital on June 30, 1895, is shown to be $10,985,203,125, or $63,330 per mile of line. The increase during the year was $188,729,312. The amount of capital stock was $4,961,258,656, of which $4,201,697,351 was common stock, and $759,561,305 preferred stock; the funded debt was $5,407,114,313; the current liabilities amounted to $616,830,156. Of the capital stock outstanding, $1,169,071,178, or 23.57% was owned by the railway corporations, as well as $437,508,841, or 9.39% of bonds outstanding. These figures show an increase in the corporate ownership of securities, probably rather due to railway consolidation than to the strengthening of reserve funds.

Stock to the amount of $3,475,640,203, or 70.05% of the total outstanding paid no dividend, and $904,436,200, or 16.90% of funded debt, exclusive of equipment trust obligations, paid no interest during the year covered by the report. In no other year since the organization of the Division of Statistics has so large a percentage of stock passed its dividends, or, except in 1894, has so large a percentage of funded debt defaulted its interest. Of the stock paying dividends, 6.89% of the total stock outstanding paid from 4 to 5%; 5.39% of this stock paid from 5 to 6%; 4.41% paid from 6 to 7%, and 3.99% paid from 7 to 8%. The total amount of dividends was $85,287,543, which would be produced by an average rate of 5.74% on the amount of stock on which some dividend was declared.

Public Service of Railways.—The number of passengers carried by the railways during the year ending June 30, 1895, was 507,421,362, which shows a decrease of 33,266,837. The number of passengers reported as carried one mile was 12,188,446,271, a decrease of 2,100,999,622 being shown when compared with figures for previous year. The number of tons of freight carried as reported by railways was 696,761,171, which gives an increase of 58,574,618 for the year. The number of tons caried one mile was returned as 85,227,515,891, indicating an increase of 4,892,411,189.

Earnings and Expenses.—The gross earnings of the railways of the United States for the year ending June 30, 1895, were $1,075,371,462, an increase of $2,009,665 for the year being thus shown. Passenger revenue was $252,246,180, showing a decrease of $33,103,378, or 11.60% for the year. Freight revenue increased $30,502,549, or 4.36%, being $729,993,462 for 1895.

The expenses of operation for the same period were $725,720,415, which were $5,693,907 less than for 1894. That important unit in railway statistics, the percentage of operating expenses to operating income, for 1895, was 67.48%; for 1890, 65.80%. The income from operation, $349,651,047, though $7,703,572 greater than it was in 1894, was yet less than for any other year since 1890. The amount of money at the disposal of railways for fixed charges and dividends is the aggregate of income from operation and income from other sources. This amount for 1895 was $482,083,180. Fixed charges for the year amounted to $425,966,921. The deduction of fixed charges leaves $56,116,259 as net income from which to pay dividends. The amount of dividends, including $673,957 other payments from net income, was $85,961,500, from which it appears that the railways of the United States closed the year with a deficit from the year's operations of $29,845,241, which was met by a decrease in accumulated surplus, or by the creation of current liabilities. The corresponding deficit for the year ending June 30, 1894, was $45,851,294.

Railway Accidents.—The number of railway employees killed during the year ending June 30, 1895, was 1,811, and the number of injured was 25,696. These figures, compared with those of the previous year, show a decrease of 12 in number killed, and an increase of 2,274 in the number injured. The number of passengers killed was 170, the number injured, 2,375. These figures give for the year a decrease of 154 in the number killed, and 659 in the number injured. The number of passengers killed is remarkably small. The smallest number killed in any of the preceding seven years was 286 in 1890. One employee was killed for each 433 employed, and one employee was injured for each 31 employed. Of the class of employees known as trainmen—that is, engineers, firemen, conductors, and other employees whose service is upon trains, it appears that one was killed for each 155 in service, and one injured for each 11 in service. The number of passengers carried for each passenger killed during the year was 2,984,832, and the number carried for each passenger injured was 213,651. The liability of passengers to accidents is better shown in the fact that 71,696,743 passenger miles were accomplished for every passenger killed, and 5,131,977 passenger miles for every passenger injured.

Conclusion.—The statistician renews his recommendations that reports be required from express companies engaged in interstate traffic, from all corporations, companies, or persons owning rolling stock which is used in interstate commerce, as also all corporations, companies, or persons owning depot property, stock yards, elevators, and the like, and from all carriers by water whose business influences interstate traffic. The further recommendation is made that Congress be requested to provide for a bureau of statistics and accounts, which shall have the right of inspection and control over the accounting departments of the common carriers.

MINERAL PRODUCTION OF THE UNITED STATES IN TEN YEARS.

The accompanying table, just issued by the U. S. Geological Survey, is so convenient a one for reference that we reproduce it herewith for the benefit of our readers. The statistics from which this table is compiled were collected by the Division of Mineral Resources of the Survey, of which Dr. David P. Day, M. Am. Inst. M. E., is the Chief.

MINERAL PRODUCTS OF THE UNITED STATES FOR THE CALENDAR YEARS, 1886 TO 1895.

(Compiled by the Division of Mineral Resources of the U. S. Geological Survey. Chas. D. Walcott, Director; David T. Day, Chief of Division.)

THE EFFECT UPON THE DIAGRAMS, OF LONG PIPE CONNECTIONS FOR STEAM-ENGINE INDICATORS.*

By W. F. M. Goss, Lafayette, Ind.

Errors in indicator diagrams may arise from several causes, one of which is the pipe connecting the indicator with the engine cylinder. It is admitted that, under the conditions of ordinary practice, the presence of the pipe does not constitute the most prolific source of error, but it can be shown that it does cause serious distortion in the form of the diagram, and it is believed that this fact merits more careful consideration than has heretofore been accorded to it. The writer has already called attention to the fact that in road tests of locomotives, where the indicator is attached to a length of pipe sufficient to bring the instrument to the top of the valve box (a length of 3½ ft. or more), a true card can be obtained only at slow speeds; and has shown that, for a speed of 300 revolutions per minute, the diagram is likely to be in error as much as 17%. These early experiments have now been followed by a more extended series, the results of which are herewith presented.

The experiments were made in connection with a 7¾ × 15-in. Buckeye engine. The power of this engine was absorbed by an automatic friction brake, by means of which a very constant load was obtained. The head end of the cylinder was tapped with two holes (a and b, Fig. 1), both in the same cross section, and hence equally exposed to the action of the steam in this end of the cylinder. One of these holes (a) was made to serve for the indicator A, the cock of which was placed as close to the cylinder as possible. The hole b was made to receive one end of a U-shaped pipe, the other end of which entered a coupling fixed in the angle plate c. The cock of a second indicator, B, was screwed to this coupling. A single system of levers supplied the drum motion for both indicators. The closely-connected indicator, A, will hereafter be referred to as the "cylinder-indicator," and the cards obtained from it as "cylinder-cards." It is assumed that this indicator recorded the actual conditions of pressure existing in the cylinder. In like manner the indicator B will be referred to as the "pipe-indicator," and cards obtained from it as "pipe-cards." It is assumed that this indicator gave a record which, when compared with that given by the cylinder-indicator, demonstrated the effect of the pipe.

The pipe fittings were all half-inch. A right-and-left coupling at d allowed the U-shaped section d f b to be removed at will and replaced by a similar section of different length. Pipe lengths of 5, 10 and 15 ft. were used, length being measured from the outside of the cylinder wall to the end of the coupling under the cock of the pipe-indicator. The pipe and fittings were covered first with a wrapping of asbestos board, next with ⅝-in. of hair felt, and finally with an outside wrapping of cloth. It is to be noted that the bend in the pipe at f is easy, and that there is a continual rise in the pipe in its course from the cylinder to the indicator. Both indicators were always well warmed before cards were taken. The boiler pressure was kept constant as nearly as possible, and the throttle was generally "full open."

A pair of new Crosby indicators was set apart for this work, with 60-lb. springs. These instruments, when calibrated under steam, gave results which were nearly identical.

The results, which are presented in the form of diagrams (Figs. 2, 3, 4, etc.), were obtained in the following manner:

Diagrams with constant speed (200 revs. per min.), constant steam pressure (80 lbs.) and constant cut-off (¼ stroke, approximately). Dotted lines show cards obtained when indicator pipes were respectively 5, 10 and 15 ft. long.

---

*Abstract of a paper presented at the St. Louis meeting of the American Society of Mechanical Engineers.

The engine having been run for a considerable period, and the desired conditions as to pressure, speed, and cut-off having been obtained, cards were taken simultaneously from the cylinder and the pipe-indicator. Two pairs of cards (i. e., two from cylinder and two from pipe) were thus taken as rapidly as convenient, after which the position of the indicators was reversed, and the work repeated. There were thus obtained four cylinder-cards and four pipe-cards, one-half of each set having been made by one of the indicators, and one-half by the other. Next, by the use of closely-drawn ordinates the eight cylinder-cards were averaged and combined in the form of a single card, and the eight pipe-cards were in the same way combined to form a single pipe-card. The two typical cards thus obtained, superimposed as in Fig. 2, constituted the record of the test. This process was repeated for each of the several conditions under which tests were made. The accuracy of the indicators used, and the constancy of the conditions maintained, were such as to make each card almost, if not quite, the exact duplicate of the representative of its set.

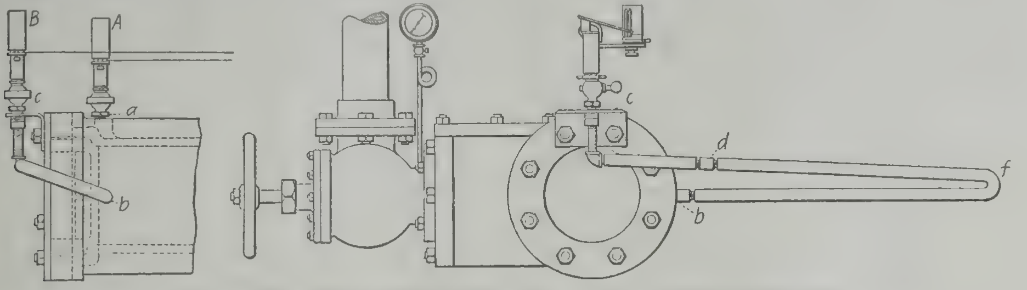

FIG. 1.--LONG PIPE CONNECTIONS FOR A STEAM ENGINE INDICATOR.

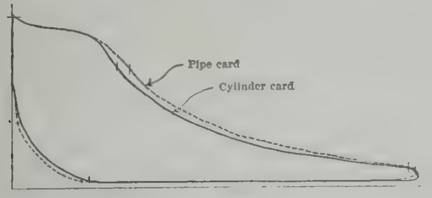

Fig.2. Five Ft. Pipe.

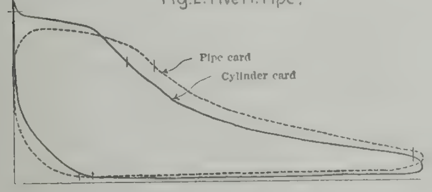

Fig.3. Ten Ft. Pipe.

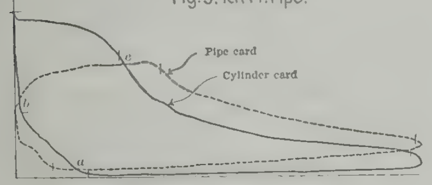

Fig.4. Fifteen Ft. Pipe

Figs. 2, 3 and 4.--Diagrams Taken With Constant Speed (200 Revs. Per Min.), Constant Steam pressure (80 lbs. and Constant Cut Off (1/4 Stroke, Approximately).

(The full lines show diagram taken with indicator closely connected. The dotted lines show diagram from an indicator with 5-ft., 10-ft. and 15-ft. pipe connections.)

By reference first to Fig. 2, it will be seen that the effect of a 5-ft. pipe is to make the indicator attached to it a little tardy in its action. Thus, during exhaust, when for a considerable interval of time the change of pressure to be recorded is slight, the lines from the two indicators agree: but during the compression which follows, the loss of sensitiveness in the pipe-indicator is made evident by its giving a line which falls below the corresponding line traced by the cylinder-indicator. Similarly, during admission there is an approximate agreement, while during the expansion which follows, the lagging of the pipe-indicator results in a line which is higher than the expansion line given by the cylinder-indicator. As a result of this lagging in the action of the pipe-indicator, its card is in error in the location and curvature of the expansion and compression curves; also in the location of the events of the stroke, and in the area which it presents. The speed at which these errors are shown to occur is moderate (200 revolutions), and the length of pipe attached to the indicator is not greater than is often used.

The general effect of a 10-ft. length of pipe (Fig. 3) is the same with that of the shorter length, but the lagging action due to the pipe is more pronounced, and all errors are proportionately greater. In this case, also, the admission and exhaust lines fail to agree, the total range of pressure recorded upon the cards being less than the range existing in the cylinder.

A still further addition to the length of the pipe brings changes (Fig. 4) into the form of the pipe-card diagram which, while entirely in harmony with those already discussed, are of such magnitude that the form of the card loses some of its characteristic features. The admission and expansion lines are lower, and the exhaust line is higher, than are the corresponding lines for the true card. While cards from pipes of 5 and 10 ft. in length present an area greater than that of the true card, the card in question (Fig. 4) from a 15-ft. length of pipe makes the area less.

It is true that the lengths of some of the pipes experimented with are excessive as compared with those commonly used for the connection of indicators, but this fact does not deprive the results of their significance. If pipes of 15, 10 and 5 ft. in length will produce the effects shown by Figs. 4, 3 and 2, respectively, it is but reasonable to suppose that pipes of less than 5 ft. in length will produce some effect. And, since the effect of a 5-ft. pipe is considerable, this length must be greatly reduced before the effect ceases to be measurable.

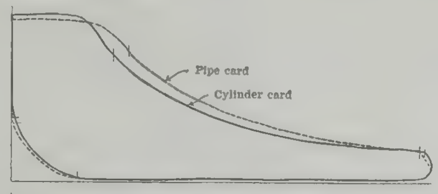

Fig. 5. 100 Revs. per Min.

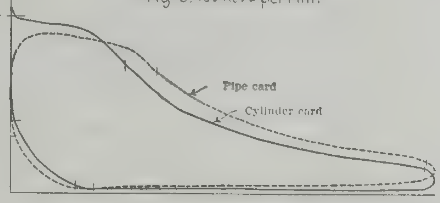

Fig. 6 200 Revs. per Min.

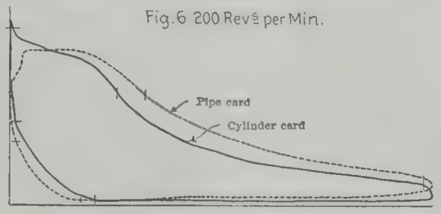

Fig. 7. 250 Revs. per Min.

Figs. 5, 6 and 7.--Diagrams Taken with Varying Speeds, but Uniform Steam Pressure (80 lbs.) Cut-Off (1/4 Stroke) and Length of Pipe Connection to Indicator (10 ft.).

Differences of speed have less effect than would be supposed in modifying the form of the pipe-card; even with a speed as low as 100 revolutions per minute, the effect of the pipe is strikingly apparent. The point of cut-off chosen for the whole series now under consideration (Figs. 2, 3 and 4), is not especially favorable for showing the modifying effect of the pipe. These considerations, together with the fact that indicator-pipes of 3 and 4 ft. in length are not uncommon, all serve to emphasize the practical value of the effects noted.

A study of the diagrams and data will make it evident that the differences are due wholly to a change in the length of the pipe. This single change, however, introduces an incidental change (1) in the clearance, (2) in the extent of surface exposed to the action of the steam, and (3) in the velocity of flow in and out of the pipe at the point of its connection with the cylinder.

The Effect of the Pipe at Different Speeds.—The effects thus far discussed are those recorded for a constant speed of 200 revolutions per minute. In considering to what extent changes of speed will modify these results, reference should be made to Figs. 5, 6 and 7, which give a series of results for which all conditions were constant except that of speed. It will be seen that increase of speed produces modifications in the form of the pipe-diagrams, which, in kind, are similar to those produced at constant speed by increasing the length of the pipe, but these changes are not great. For example, increasing the speed from 100 to 200 revolutions per minute (Figs. 5 and 6) produces less change than increasing the length of the pipe from 5 to 10 ft. (Figs 2 and 3). The fact that an engine runs slowly, therefore, does not seem to justify the use of an indicator at the end of a considerable length of pipe. Slow running reduces the error; it cannot be depended upon to eliminate it entirely.

The Effect of the Pipe at Different Cut-offs.—The relative effect of the pipe at different cut-offs, other conditions being constant, is shown by Figs. 8, 9 and 10. It will be seen that the differences of pressure recorded during expansion by the two indicators (pipe and cylinder) are approximately the same for all cut-offs; but the relative effect of these differences upon the area of the diagram is most pronounced upon the smallest, or shortest, cut-off card. The fact that in Fig. 10 the steam line on the pipe-card rises while that of the cylinder-card declines, constitutes a good illustration of the slowness with which the pressure in the pipe responds to that in the cylinder.

Table I. gives a comparison of the mean effective pressures and of the steam consumption per horse power per hour calculated from the pipe and the cylinder diagrams.

TABLE I.—Errors in Indicator Diagrams Due to Long Pipe Connections.

No. of figure representing diagram.	Excess (+) or Deficiency (—) as Shown by Pipe Diagram.			
	Mean effective pressure.		Steam consumption per HP. per hour.	
	Lbs.	Per cent.	Lbs.	Per cent.
2	+1.2	+3.7	—0.1	—0.5
3	+2.7	+8.5	—0.4	—1.7
4	—1.5	—5.0	+11.7	+45.9
5	+3.0	+8.8	—2.0	—7.2
6	+2.2	+6.6	—0.4	—1.7
7	+5.3	+18.7	—1.0	—4.2
8	+6.5	+35.3	+11.5	+47.9
9	+4.2	+12.8	—0.4	—1.7
10	+1.4	+3.4	—6.8	—23.6

All percentage values are based on results from cylinder diagrams.

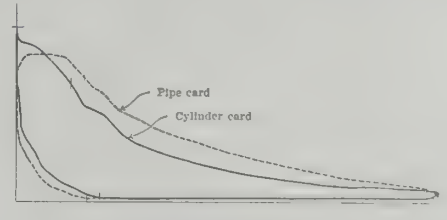

Fig. 8 Cut-off 1/8 Stroke

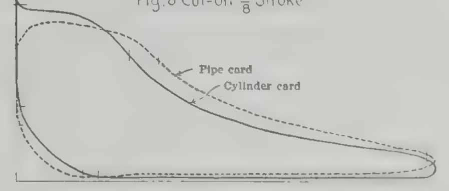

Fig. 9. Cut-off 1/4 Stroke

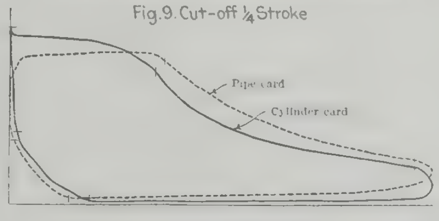

Fig. 10. Cut-off 1/3 Stroke.

Figs. 8, 9 and 10.--Diagrams Taken with Varying Points of Cut-off, But Steam Pressure, Speed and Length of Indicator Pipe Connections the Same as in Figs. 5, 6 and 7.

The principal conclusions drawn from the data presented is that if an indicator is to be relied upon to give a true record of the varying pressures and volumes within an engine cylinder, its connection therewith must be direct and very short.

◆

JAPANESE COMPETITION WITH AMERICAN MANUfactures has been a bugbear for some time, and all sorts of silly items have gone the rounds of the press. One which had especially wide currency was that Japanese bicycles were imported and sold for $12 in San Francisco. An interesting comment on this is found in a recent newspaper interview with W. Araki, of Osaka, Japan, in which he is quoted as saying:

> Our people have in the past dealt largely with English firms, but are coming to see the superiority of American manufactures in many lines. For instance, we have been buying our bicycles from Birmingham manufacturers heretofore, paying from $50 to $80 for them, but I now find that better ones can be bought in this country for less money. It would be a first rate idea for American bicycle firms to send samples to Osaka, as our bicycle demand is growing rapidly.

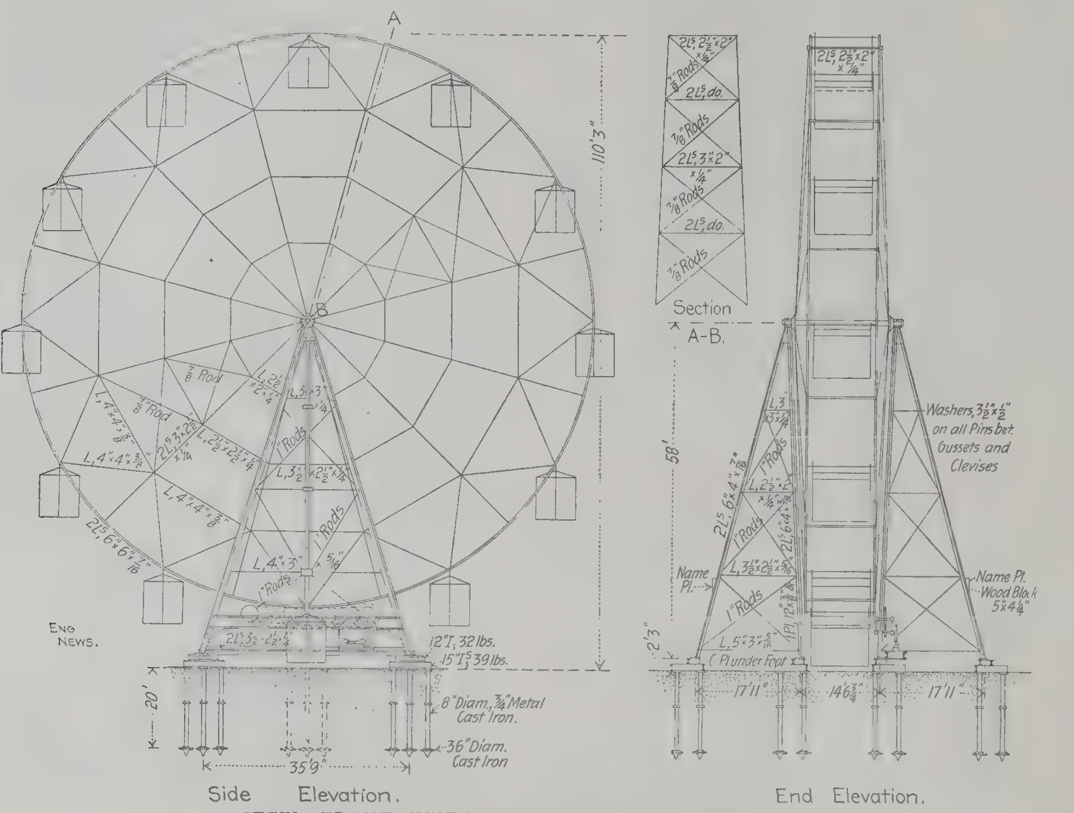
Mr. Araki comes to this country, according to the "Chicago Inter-Ocean," to obtain samples of American goods for the Osaka commercial museum, and invites all American manufacturers to send samples of their products, and their catalogues to the Osaka Commercial Museum, Osaka, Japan. The Japanese government will pay the charges for transportation and space for exhibits is free.

Respecting the idea that Japanese cheap labor is likely to compete successfully with American, it is stated that the fatalities of the late war have greatly increased the rates of wages. Ordinary workmen now receive 50 cts. per day and skilled workmen as high as $2 per day.

A STEEL FRAMED WHEEL 100 FEET IN DIAMETER.

A steel frame wheel, 100 ft. in diameter, on the general plan of the great Ferris wheel at the Columbian Exposition, was recently built by the Phoenix Iron Works, of Phoenixville, Pa., at Bergen Beach, N. Y., the wheel being similar to the one built by the same firm for the Atlanta Exposition last year.

The foundations are 18 cast-iron piles, 8 ins. diameter, with disks 3 ft. diameter, sunk by water jet to 20 ft. below the surface of the ground. The lower 8 ft. of this depth is seashore sand, which is overlaid with about 8 ft. of meadow mud, and that again overlaid with sand filling. The tower legs are made of angles and flats, and are braced with rods and angle struts, The axle of the wheel is of 8¼-in. square steel, turned to 8-in. journals at the ends; the hubs are of cast steel, the spokes, struts and rims are of angles, and the transverse bracing is of adjustable rods.



STEEL FRAME WHEEL AT BERGEN BEACH, N. Y.
The Phoenix Bridge Co., Phoenixville, Pa., Builders.

The motive power is a double cylinder steam engine of 15 HP., which was calculated to drive the wheel fully loaded at a rim speed of 2 ft. per second, making one revolution in about 2½ minutes. The driving gear consists of an endless flat link chain on sprocket wheels, which engages the teeth of a cast-iron sprocket wheel bolted in segments to the rim of one disk. There are 12 cars, 7 × 10 ft., with a capacity of 14 passengers each. The cars consist of angle iron frame work, clamped to and suspended from shafts which turn in journal boxes secured to the rim angles. They are covered with awnings and enclosed with heavy wire netting. A wind pressure of 50 lbs. per sq. ft. was assumed in making the computations.

The same firm has also built, at Coney Island, for Mr. Geo. C. Tilyou, a wheel of the same size and general design, but with cars constructed of angle and frame work enclosed with wood and glass for service in stormy weather. To resist the greatly increased effect of wind on the enclosed cars, the wheel and towers were made heavier throughout, and in addition the rim is stiffened laterally with straight I-beams, secured to the spokes, as shown by dotted lines, on the outline of the wheel. This wheel is founded on piles, similar to those at Bergen Beach, but as there is no deposit of mud at this point the disks are sunk only 10 ft. below the water level in the sand. The firm has also built a third wheel of the same dimensions at Washington Park, on the Delaware River, below Philadelphia. It is exactly like the wheel at Bergen Beach, except that the foundations are of masonry. We are indebted to Mr. H. H. Quimby, Principal Assistant Engineer, for the blue prints and information.

THE PRODUCTION OF METAL BARS BY EXTRUSION AT HIGH TEMPERATURES.*

By Perry F. Nursey.

The ingenious metallurgical process which I now have the privilege of bringing before the Institute is the invention of Mr. Alexander Dick, and deals with the production of all kinds of metallic sections, from a simple round wire to complex designs which it would be impossible to roll, by forcing metal heated to plasticity though a die under hydraulic pressure. The principle is simple enough, being nothing more than that employed in the manufacture of bricks, drain-pipes, and similar articles. It is, however, the application of that principle to the purpose under notice that constitutes the ingenuity and originality of the invention, and which marks it as a substantial advance in metallurgical practice.

I do not forget that the principle of extrusion has been applied in the production of continuous lengths of leaden pipes and wire, and also of leaden rod for the manufacture of projectiles for small arms, and for other purposes. In those cases, however, the lead is pressed at a comparatively low temperature, whilst in the present instance the metal is operated upon at a very high temperature, namely, that of plasticity, or about 1000° F., and which varies considerably with different metals and alloys.

The process of manufacture consists in placing the heated metal in a cylindrical chamber, at one end of which is a die. Upon pressure being applied at the opposite end the plastic metal is forced through the die, issuing therefrom as rods or bars of the required section and of a length governed by the quantity of metal placed in the receiver. This pressure-chamber has not only to withstand the high temperature of the contained metal, but has likewise, whilst under the influence of that temperature, to meet the severe strain brought upon the interior by the resistance of the metal to the pressure of the hydraulic ram in forcing it out through the contracted area of the die. Hence the first and most important point to be settled was the design of the cylinder and the material of which it should be constructed.

At starting several cylinders were made, some of cast and some of wrought steel, in order to ascertain which material was best suited for the purpose. The chamber was 24 ins. long and 6 ins. diameter internally, the walls varying in thickness from 3 ins. to 6 ins. Surrounding the cylinder was an annular chamber heated by a coke fire, the object of which was to maintain the plasticity of the metal during the operation of pressing. In practice, however, it was found that the strains set up by the unequal expansion and contraction of the walls of the cylinder, added to the internal working pressure, soon developed cracks, thereby rendering the cylinder useless.

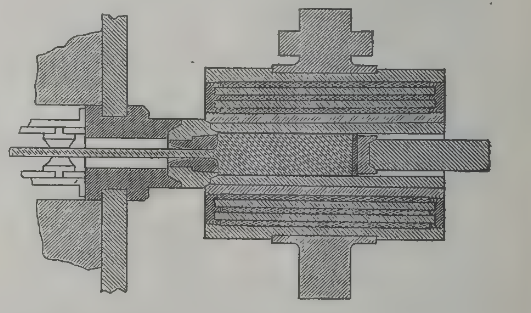
Nothing daunted by failure, Mr. Dick set to work to devise other means whereby he hoped to accomplish his end. The difficulty respecting the pressure-chamber, or container, was eventually overcome by dividing up the container into sections composed of concentric steel tubes alternating with annular spaces packed with a dense non-conducting material. This arrangement is based upon the principle, that whilst steel, when heated to a high temperature, loses its integral strength, as proved by Mr. Dick's experiments, yet at low temperatures it will retain its full power to resist pressure; so that a cylindrical chamber formed of several comparatively thin walls, and protected from extreme heat, will resist pressure better than a chamber having a thick solid wall heated to a high temperature. A chamber surrounded by comparatively thin walls heated to a comparatively high temperature is not so injuriously affected by variations of temperature as a similarly heated chamber having a solid wall of greater substance.

By this compound system of construction, the liner, which is exposed to the extreme heat of the metal, may be made with a comparatively thin wall, and will not be liable to be fractured by unequal heating and cooling, and consequent expansion and contraction. Further, in order that it may be capable of successfully resisting pressure, it is reinforced by means of the surrounding steel tubes, which, although of themselves thin, are insulated and supported by a dense packing of non-conducting material, and are therefore kept at a comparatively low temperature and in a condition to offer the greatest resistance, which condition is further mechanically influenced by a stout steel outer casing.

Another problem which took some time to solve was the selection of an efficient non-conducting material. The main conditions here were that the particles of the material employed should be capable of being densely consolidated, should not seriously affect either the liner or the outer cylinders, nor melt nor become decomposed at a high temperature. After experimenting with a variety of substances, Mr. Dick found that the best results were obtained from crushed granite mixed with a small proportion of borax. This compound satisfactorily fulfilled all the necessary conditions, and was therefore adopted as a non-conductor.

The apparatus as now constructed and in daily operation is 16 ft. in length, 6 ft. wide and 5 ft. high over all. It consists mainly of the compressing cylinder or container and the hydraulic ram. A longitudinal section of the container is shown herewith. The container, which is 2 ft. long and 2 ft. diameter externally, has an inner liner of cast steel. The internal diameter of the liner varies in different containers from 5 ins. to 8 ins., according as to whether it is wanted for pressing a small or a large charge, the container being changed as required. The liner is enclosed with a series of cylinders of ordinary mild steel spaced about ¾-in. apart, the annular spaces being filled in with the non-conducting material. The container is mounted on trunnions and fitted with worm-gearing for bringing it to a vertical position for being charged with metal and restoring it to the horizontal for the operation of pressing.

Great care has to be exercised in making the die-plates, the material of which is tungsten steel. They are formed with either one or several openings, each opening being of the section required to be given to the article to be produced. The edges of the openings in the dies are beveled, so as to give free access to the metal under pressure, and to more perfectly condense it. The die-plate is mounted in a holder, in which it is easily fixed, or from which it is readily removed, as different sections are required to be pressed. As it is necessary to heat the die and its holder previously to each pressing operation, the die is fitted into a shouldered recess in the holder, which is coned to seat into a hollow metal block. This block is firmly held in position during the operation of pressing by a pair of gripping jaws actuated by hydraulic power.



Longitudinal Section of Pressing Cylinder for Producing Metallic Bars by Extrusion; Alexander Dick, Inventor.

The metal is forced out of the container and through the die by a hydraulic ram 18 ins. in diameter, and working under a pressure of 2 tons per sq. in. The ram has a prolongation or extension, of reduced diameter, which forms the plunger of the container, entering it at the opposite end to the die. A different plunger is used with each container, the diameter varying to suit the internal diameter of the container. On starting to work each day the container is first heated up by gas with a Bunsen burner, which quickly brings the liner to the temperature necessary to prevent the first charge of metal getting a chill. The container does not require reheating, as the liner remains red-hot after each run.

---

*From a paper read at the meeting of the Iron and Steel Institute, May, 1896.

The working of this ingenious system of production will be best described from my own observations during a recent visit to the Delta Metal Works, Pomeroy St., New Cross, London, where it has been in regular commercial operation for some time. Upon that occasion the machine was running on an order for Delta metal rods 12 ft. long by 1 in. diameter. Of course, much greater lengths and much heavier sections are turned out as required. The sections produced ranging from light sections, such as wire weighing about 1-100 lb. per ft., to heavy rounds, hexagons and squares weighing 40 lbs. and over per ft. The die in use on the occasion of my inspection had four openings, thus producing four lengths, or an aggregate of 48 ft. of rod at the same time.

A charge having just been put through, the opening at the front end of the container (that next the die) was closed by a removable plate or stopper, and the container was turned into a vertical position. A charge of 1½ cwt. of molten metal was then poured from a ladle into the container, and was allowed to stand for about six minutes, so as to acquire a plastic condition. The diameter of the plunger and that of a loose block which is placed between it and the charge (for a purpose which I will shortly explain) being less than the diameter of the steel liner, the plastic metal when under pressure would be forced backwards between the block and the liner were it not restrained. In order to prevent this back-flow taking place, a dished steel check-disk, which is less plastic and more rigid than the heated metal at the working temperature, is first placed on the top of the charge, and when the pressure is brought on, the disk is expanded and completely fills the bore of the liner, thus effectually preventing the backflow of the metal.

Upon this check-disk was then placed the loose steel block just referred to, which, having been previously heated, prevents the cold end of the plunger chilling the charge of metal. The plunger being of smaller diameter than the liner, there is no fear of the latter becoming chilled by the former. To preclude the possibility of such an occurrence, the back of the loose block is recessed to receive a corresponding projection on the front end of the plunger, which is thus kept horizontal in its forward travel and prevented from coming in contact with the liner.

The loose block having been inserted, the container was brought into a horizontal position, the stop plate removed, and the container run up to the die-block, which, with the die, had been previously heated. The hydraulic pumps were then started, and in four minutes the charge was expelled and had become converted into four 1-in. rods, each measuring over 12 ft. in length. The clips were then released and the ram continued its forward travel, pushing out the remaining metal, or stump, together with the die and its holder, as well as the check-disk and the loose block, leaving the container perfectly clear for a fresh charge. The rods were at once cut off from the stump or fag end of the charge to the exact length required and removed. The die and holder were then replaced by others, the container turned over into a vertical position, the stopper fixed in place, a fresh charge of metal teemed in, and as soon as it had become plastic the operation of pressing was again proceeded with. I may mention that the rate of travel of the ram can be varied to suit the size of the charge or the special nature of the output.

With regard to the physical characteristics of the bars thus produced, it is obvious that, owing to the great pressure put upon the metal, its quality must necessarily be greatly improved, in the same way that Whitworth steel is improved by compression. In the first place, it is found to be perfectly homogenous. The actual increase of strength in extruded bars over that of hot rolled bars of the same metal varies with the nature and composition of the metal or alloy. Taking ordinary yellow metal, the increase in tensile strength is 24%, with a proportionate increase in elongation. Some tests made at Woolwich Arsenal with Delta metal bars produced by extrusion show a tensile strength of 48 tons per sq. in., with 32.5% elongation on 2 ins., against 38 tons per sq. in. tensile strength and 20% elongation of rolled bars of the same metal.

I have stated that at the time of my visit the mode of procedure was to charge the container with molten metal. The objection to this method of working is the delay occasioned at the press in waiting for the molten charge to set or become plastic, besides which there is the time occupied in various detail operations attending the charging of the container with molten metal. The result is that the average rate of working is only 25 charges per day of 10 hours. This method of working has since been improved upon by Mr. Dick, and the container is now charged with billets after they have been heated to the point of plasticity in a furnace. With this method of working the output is doubled, easily reaching 50 charges and more per day. The labor cost per ton on the finished work is very small, being only the wages of two men and a boy per machine.

A larger press also is in course of construction which will have a 20-in. ram, and will be capable of turning out heavier work than any yet produced. Besides being in operation at the works already mentioned, the system is being worked under license in the Midlands, and it has also been adopted in the Delta Metal Works at Dusseldorf.

Mr. Dick is at the pesent time engaged upon experiments with the view of producing sections in iron and steel by this process.

SOME FACTS ABOUT SLOW SAND FILTRATION OF WATER.

By Mrs. Percy Frankland.

Every one who has carried out systematic bacteriological examinations of any given water supply is struck with the fluctuations which occur in the bacterial contents of filtered water.

In the case of the London water supply, for example, Prof. Percy Frankland, in his monthly reports to the Local Government Board, showed that one and the same company delivered water after filtration in which the bacteria present varied from 2,270 per cu. cm. in January to 49 in September. Until we can satisfactorily account for such variations in the bacterial quality of the filtrate we cannot hope to eliminate the present element of uncertainty which surrounds the production of a good filtrate. The question has given rise to much discussion, and it is, therefore, with special interest that we note some recent contributions to our knowledge of this subject.

In a previous issue of this journal (March 14, 1895,) attention was directed to some of the other factors which must be held responsible for an efficient filtrate and amongst these the formation of surface slime on the filter beds was mentioned.* We know that when the process of cleaning a filter has been carried out the latter does not immediately yield satisfactory results; the coating of slime has to be encouraged, and the time which elapses before a filter gets into condition will vary with different waters and probably at different seasons of the year. For example, in the case of the Zurich water supply, where pure water as derived from the Lake of Zurich is used, it is found that on renewing the sand in a filter, it is only after from 3½ to 36½ days that the water gets into proper working order and yields a satisfactory filtrate. The time required for such conditioning of a filter is, of course, exceptionally great in a case like this, in which a comparatively clear and bacterially pure water is being filtered; on the other hand, this delay is more than compensated for by the greatly extended length of time that filters dealing with such description of water can be kept working, from three to four years being the period allotted to them, and during which they are found capable of yielding an exceedingly pure filtrate.

Now, although the bacterial condition of the raw water may have a great deal to do in determining the microbial character of the filtrate, yet it would appear from recent researches that if the filters are working at their best, the filtrate does not reflect the fluctuations of the raw water; if, however, bacterially bad water chances to coincide with a period when the filters are not efficient then the result is immediately visible in greatly increased numbers of bacteria in the filtrate.

This point is brought out by the Zurich water supply. The average number of bacteria present in the lake water was, one year, 123 per cu. cm., and in the filtered water, 24 per cu. cm.; the following year, however, in consequence of the lake freezing, the average for the raw water was raised to 583 per cu. cm., but the filtered water exhibited no corresponding increase, the average for the year being only 23 per cu. cm. This satisfactory result was entirely ascribed to the excellent working of the filters.

A confirmation of these facts in greater detail has been lately furnished by Dr. Kurth in the course of his bacteriological examinations of the Bremen water supply delivered from the river Weser and submitted to sand filtration before delivery.

In the winter months, when rivers are often in flood, the number of bacteria present may often rise enormously in excess of what are found at other times; thus Dr. Percy Frankland has found as many as 56,000 to 121,000 per cu. cm. in the rivers Thames and Lea in the winter, whilst in the summer months the numbers present in these waters are represented by much smaller figures, such as 1,070 to 3,000. This condition of the raw water in the winter was frequently strikingly reflected in the filtrate.

Dr. Kurth fully confirms these observations, but having access to the individual filters he has been able to ascertain in detail how it is that the filtrate becomes affected when flood water is supplied to the filter beds. These investigations bring out very clearly not only the manner in which the bacterial condition of the raw water affects the filtrate, but also how efficient filtration may be successful in evading the deterioration of the filtrate in times of flood. The following investigations illustrate these points very clearly: The number of bacteria in the raw river water rose suddenly between Jan. 20 and 24, from 5,000 to 30,000 per cu. cm. After the breaking up of the frost between Jan. 15 and 22, the opportunity was taken of cleaning as many filter beds as possible, and only two beds, Nos. 1 and 7, which were left to the last, had not been touched when the investigations were made. So that here we have a coincidence of bacterially bad water and freshly cleaned, or, in other words, inefficiently working filter beds. As was to be expected, all the effluents from the recently cleaned beds exhibited, on Jan. 25, as many as from 500 to 1,200 bacteria per cu. cm., but, on the other hand, despite the access of this flood-water, the filters which had not been interfered with, exhibited an excellent filtrate only 90 and 100 per cu. cm., respectively, being found. Dr. Kurth states that he repeatedly found that the admission of flood water to the filter beds did not affect the filtrate if it occurred when the filters were working at their best, say during the middle or towards the end of the period in which they are in use, but that its effect was readily visible when the filters were not yet in condition. Thus, on another occasion, between Feb. 24 and March 1, the bacteria in the raw river water rose from 4,000 to 29,000 per cu. cm., the filters, however, which were all 13 to 20 days old, that is to say, 13 to 20 days had elapsed since the last cleaning, yielded excellent filtrates, containing from 66 to 86 bacteria per cu. cm.

In conclusion, reference may be made to some interesting investigations of Dr. Kabrhel, which have been recently published, on the length of time necessary for the disappearance of particular bacteria, present in the raw water, from the filtrate. These experiments are of importance as in the event of pathogenic micro-organisms being present in the raw water it is of great consequence to ascertain whether the filtrate may become infected, and, if so, for how long.

For this purpose he constructed an experimental filter and supplied it with water infected with a particular microbe, easily destinguished from ordinary water microbes by the pigment it produces on gelatine surfaces. He states that for a considerable time after he ceased supplying the filter with this microbe and had passed ordinary water through, he found this particular micro-organism in the filtrate. Thus he inclines to the opinion that should water infected with disease germs gain access to a filter, the latter may retain them for considerable periods of time in its interstices and that the passing of succeeding volumes of water would tend to wash them into the filtrate and even after a considerable lapse of time render the latter obnoxious.

The efficient sand filtration of water is a hygienic precaution of the highest order, but it must yet only be regarded as a precaution and not necessarily endowed with infallibility. Valuable as such measures undoubtedly are in the purification of water, they do not render us independent of the nature of our supply, and the oldest consideration must still remain the first, the acquisition of the purest source possible for our public water supplies.

---

*The conclusions drawn from the Lawrence experiments on water filtration indicate that the efficiency of new filters, or filters after cleaning, depends quite as much, to say the least, upon the formation of a coating upon the surface of each sand grain as upon the surface of the whole bed, this sticky matter evidently retaining the bacteria.—Ed.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32*d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The somewhat startling announcement was made a few weeks ago that sand dredged from the Passaic River and used in paving work at Newark was responsible for a marked increase in typhoid fever in that city in 1895. This statement was credited to Dr. H. C. H. Herold, President of the Newark Board of Health, to whom we at once applied for information. Dr. Herold kindly sent us an extract from a report made by him on April 21, 1896.

An examination of the extract leads us to doubt whether there was any relation between the sand in question and typhoid fever. The report states that there were 88 cases of typhoid fever in 1894 and 36 deaths, while in 1895 there were 148 cases and 39 deaths, or an increase of nearly 70% in cases and only 8% in deaths. The figures indicate a mortality of 40% in 1894 and 25½% in 1895. Even the latter figure seems to be an excessive percentage of fatal cases. We suspect that not all the cases occurring in 1895 were reported, but that there was an improvement in this respect over 1894.

Turning now to the arguments in support of the sand theory we find that these are: (1) The detection, on examination, of the bacillus "coli communis" and a bacillus "resembling typhoid" in the sand in question and the absence of such bacteria in other sand and dirt about the city; (2) the increase in the number of cases was in the latter part of the year and the paving was carried on from July to December. Regarding (1) it may be said that as the sand was taken from the bed of the sewage-polluted Passaic, the bacteria named were naturally present, while as the other sand had not been subjected to sewage or other excrementitious matter the bacteria were naturally absent. As to (2) it is well understood that typhoid fever is more prevalent from August or September until November or December; in addition, the improvement in reporting cases may have begun in July.

A further argument against the theory advanced is that the typhoid bacillus develops in the digestive and not in the respiratory organs, so that it is unlikely that the extra cases could be accounted for by the theory under discussion. Moreover, if the people of Newark succumbed to germs which float from river sand on the few streets where paving was being put down, what would be expected in Jersey City, where the sewage-polluted water was being used throughout the whole city at the same time?

The extract concludes with a request for "the immediate stoppage of the use of this sewage sand on our streets," on the ground that it causes typhoid fever, an assumption which we do not think is borne out by the data presented, or is even remotely probable.

So much has been said in the newspapers of late concerning the prospects of compressed air as a motive power for street car propulsion, that a few words as to just what is being done and what is likely to be done may be of interest. In the first place the reason why the New York street railway companies are experimenting with compressed air is that Manhattan Island is the only place in the United States where street railway companies are not allowed to erect overhead wires. The cable is in use on some of the north and south lines; but its first installation is enormously expensive, and in view of the rapidly waning popularity of cable traction for street car lines, the managers of street railway properties hesitate before incurring an enormous expense for a plant which may be obsolete in a few years. Further, for many of the cross-town lines the traffic is hardly sufficient to support a cable railway.

The managers of the various street railway lines have several alternatives offered them. They can keep on using horses, which means heavy expense and also loss of traffic; they can adopt some underground electric system, such as the General Electric's conduit system, or the Westinghouse magnetic switch system; but either of these systems are regarded as more or less experimental, and the managers hesitate to put down any sort of plant in the street where any possibility exists that it may all have to be torn up again.

In this dilemma the managers of the air propulsion systems come along with great claims for the excellence and economy of their plan; and, we presume, with guarantees to stand the expense of the trial in case the success claimed is not secured. The street railway managers, therefore, feel that they have everything to gain and nothing to lose. If the air motors handle their traffic at a reasonably low cost, they will doubtless adopt it, at least for the cross-town lines with light traffic; if it proves a failure they suffer no loss, and there is no trouble over torn-up tracks, as would be the case in experimenting with any cable or electric system.

Mileage tickets are about to be issued by the Northeastern Ry., of England, and from a note in London "Engineering" this appears to be an entirely new departure on British railways. The books are to be for 1,000 miles, are for first-class passengers only, and the price, which will seem high to an American, amounts to $25.45 in United States money. It is to be remembered, however, that the British first-class car is nearly equivalent to our parlor car; and as American parlor car rates are usually about ½ ct. per mile, it would seem that the rate is almost identical with what an American traveler pays who uses a mileage book at 2 cts. per mile) and rides in a parlor car. The English mileage books, however, have so much red tape in connection with them that it is doubtful whether they will prove popular. Their use is restricted to the purchaser, members of his family or his guests; but a certificate must be made out and signed by the purchaser for every such user except himself. Further, the purchaser of a book is not relieved of the bother of going to the ticket-office before every journey as is the case here. Instead, he must be on hand at the "booking office," present his mileage book and his "certificate" duly signed, and witnessed we presume, have the ticket-seller tear off coupons for the journey he proposes to take, and receives at last a first-class ticket in exchange. What would happen in case after partially completing his journey he should decide not to stop at the place his ticket called for, we do not know; but we presume he would have to go back to his starting point and begin all over again. It may be noted, further, that the books are limited to one year, and that for any journey of less than 10 miles, 10 coupons are taken from the books; also that these books are not entrusted to the ordinary ticket-seller. Applications for them must be made in writing to the Superintendent of the Northeastern Ry., accompanied by a remittance, by the full name and address of the applicant, and we presume also his pedigree, though this is not stated.

Probably the Englishman who travels first-class on the Northeastern Ry. will vote the mileage book system a nuisance, and will wonder how it is that travelers in America use mileage books so extensively.

In another column of this issue a correspondent points out the difficulties which lie in the way of the adoption of the metric system and proposes, as a solution of the difficulty, that a duodecimal system of arithmetical notation be adopted in place of the present decimal system.

The scheme is an interesting one—as a curiosity; but we see no likelihood that it can ever be anything more. The practical aspect of this proposal is considered editorially in the last number of London "Engineering," which says among many other things:

> In a country that had no records the introduction of such a system would be quite easy. But we are the heirs of the ages, and have a vast patrimony of knowledge that would become depreciated by the change. It must be remembered that quantities expressed in decimal notation cannot be converted into their duodecimal equivalents by any process of subtracting a percentage. Except in simple cases, the conversion cannot be carried on mentally, but must be done on paper by means of repeated divisions by 12. All the numerical results of scientific research would require to be altered with the new notation, and the elaborate tables of calculated results which are possessed by engineers and others would become almost valueless, and often it would be as easy to recalculate any particular example as to reconvert it.
>
> Engineers, however, take readily to changes when they see the necessity of them. Their career is a prolonged attack on new problems, and as a rule they welcome novel weapons of attack, provided they are more effective than the old ones. It is the general community that needs to be considered in the present case. If the duodecimal system were introduced, we should have our familiar numerals bearing their old significance when they stood in the position of units, and a new significance when they were in any other position. The figure 6, for instance, would be the friend of our youth, but 60 would be an utter stranger, assuming the name and carrying the face and habiliments of a former acquaintance. We are told that metrical measures are beyond the comprehension of the masses, but, at any rate, they have an individuality of their own which prevents them from being confounded with any others. No one reading that a piece of land is 100 metres long can make the mistake of imagining it to be 100 yards. The man who is invited to partake of half a litre of beer will not expect half a pint. The dressmaker would easily comprehend that 10 metres of silk went as far as 11 yards used to do. But we very much question whether a senior wrangler could be relied upon to put down a sovereign for an article priced at 18s. As for ordinary folks, even a surgical operation could not put into their heads that a shilling and sixpence were sixteenpence.

The only way, says "Engineering," by which this confusion could be avoided would be to select entirely new characters and names for the numerals of the duodecimal system. But this again lands us on the other horn of a dilemma. The greater mass of the adult population would never learn the new notation. Not all the powers of the strongest government could compel the abandonment of their old methods of notation.

It appears to us that this is by no means an overstatement of the difficulties which would beset such a revolution in the arithmetic of the civilized world. There is one other thing respecting this proposed change, however, which should of itself be sufficient to dismiss it from consideration as a practicable scheme. That is the fact that such a reform would be certain to be opposed by the masses of the people. It was possible for a Napoleon to turn things topsy-turvy, in the reckoning of time and in a thousand other of the affairs of every-day life; but to-day practically all the civilized world is under popular government. What congressman would dare to sign his political death warrant by voting to compel people to reckon by dozens instead of by tens!

We, some weeks ago, expressed the opinion that this factor of popular opposition was likely to opperate to delay indefinitely the adoption of the metric system. We feel still more certain that it will prove a perpetual barrier against any such sweeping innovation as a duodecimal notation.

THE EVILS OF FICTITIOUS ACCURACY.

If a man were to drive a load of hay upon a public weighing scale and were to be informed by the weighmaster that the load weighed 2117.635 lbs., he would either conclude that the weighmaster was either a fool or a joker, for everyone knows that such scales do not weigh to the hundreth or the thousandth of a pound, and even if they did the value of articles commonly weighed there is such that it would be ridiculous to attempt to weigh them to a fraction of a pound. All through practical everyday business life, in the measuring and weighing of commerce or manufacture, the rule holds good that no one thinks of giving or asking for any greater accuracy than the value of the articles measured makes needful, or than the tools used for measuring will furnish. We measure the wheel-base of a locomotive, for example, in feet and inches, the capacity of a tank in cubic feet or gallons and of great reservoirs (practically) in thousands or millions of the same units.

Thus, in numberless instances that we might name, the rule holds good that accuracy is sought only when it is needed, and it is not claimed directly or indirectly, unless it has been fairly obtained.

But when we turn now to certain departments of engineering, for the most part those departments which have been transferred in recent years from the laboratory to the field of commercial testing, we find a remarkable neglect of those common-sense rules with respect to accuracy which we have observed above. We find, for example, engineers writing down the elastic limit of a piece of steel as 34,396 lbs., when the method of determining the elastic limit is such that there may be a variation of perhaps 500 to 3,000 lbs. between the results obtained by different observers from the same piece.

Again let us take the steam engine indicator, an instrument which has accomplished wonderful results in the improvement of engine practice. Let us sum up the errors due to lost motion in the joints, spring in the arms, friction and inertia of the piston, friction and condensation of the steam in the pipes,* breadth of the pencil line of the diagram, erratic motion in the tracing point of the planimeter and errors in the planimeter mechanism, and then decide whether it is wise to set down the horsepower computed from the diagram to hundreths.

For a still more striking example we may take the tests by calorimeter of the moisture in steam. We find in one test which we select almost at random, the quality of the steam set down to three places of decimals. In another, a pamphlet received only this week, we find the following:

Quality of the steam (dry steam = unity)	1.01443
Moisture in the steam	0.000000
Degrees of superheat	26.499
Percentage of superheat	1.443

Now we will suppose, for the sake of argument, that the modern calorimeter will measure the moisture in steam with a probable error of a tenth of a per cent provided a fair sample of the steam is secured. The fact still remains that according to the best information attainable, no experimenter can ever be sure that the sample of steam he is testing does not vary in moisture by from one-half to one per cent. from that which the boiler is actually delivering. In the light of this knowledge, how absurd appears the setting down of figures which pretend to give the quality of steam to hundredths or thousandths or ten thousandths.

The errors in determination of the heat value of fuels by another sort of calorimeters were discussed in our issue of June 11, and it was then shown that to base records of boiler efficiency on such determinations was like measuring cloth with a tape measure of rubber-elastic.

So we might continue and show how in many other departments of engineering work, some engineers (not all by any means) habitually set down figures and report results with an apparent accuracy which is warranted neither by the limit of error of the instrument nor by the importance of the matter at hand; but it is unnecessary to carry the illustrations farther. Every engineer will recall many instances, we are sure.

And now let us see what harm is done by this practice. The first and greatest harm, it appears to us, is to effect an actual deception. If an engineer reports that an engine develops 512.78 HP., anyone is justified in concluding that the test is made with instruments and methods which effect the determination to a hundredth of a horse-power. If a layman is told that a piece of steel showed an ultimate strength of 72,185 lbs., he supposes, of course, that ultimate strength is determinable to a single pound. If an engineer in a report sets down that a certain boiler made 0.34% dryer steam than another boiler and the maker of the first boiler prints this report and puts these figures in large display type, is not the public justified in supposing not only that the test was accurate to a hundredth of a per cent., but that there is some practical importance attaching to a variation of a hundredth of one per cent. in the quality of steam?

In the second place, we are much inclined to believe that engineers do harm to themselves and to the profession by this objectionable practice. Any man of common sense who finds that the figures in an engineer's report appear to show an accuracy which is far from being reached, has his faith in the entire report materially shaken. After he has found repeated instances of this in the reports of different engineers, his confidence in the engineering profession begins to fail. The public is still too much inclined to look on engineers as "a lot of theoretical chaps." Such things as these in engineers' work give some excuse for supposing that the profession is better versed in mathematics than blessed with common sense.

Still another respect, in which harm is done when engineers' reports are loaded with useless decimals, is that the important figures are obscured. The number 100, for example, is easily grasped by the mind. The number 101.376198 is of very nearly the same in value, but it is an effort for the mind to grasp that fact. Now all written matter whatever, be it the report of an engineer or anything else, has only one purpose—to convey ideas to the mind. And the more simply and directly the important ideas are presented, the more readily and surely will the mind grasp them. The engineer who encumbers a report or a paper with a lot of decimals or tacks meaningless cents onto figures which run into the thousands of dollars, weakens by so much the force of his work, and the extent to which it will be read and understood.

But in fairness to those we are criticising, it is well to inquire how it comes about that so many engineers are addicted to the immoderate use of decimals. There is nothing to show that the practice was or is ever adopted with the intention to deceive either clients or the public with an exaggerated notion of the accuracy of an engineer's work. It appears to us that it comes merely from the habits formed in the school, of carrying out results to several places of decimals to reduce the errors of computation. In all work with engineering instruments, of course, whether they be the transit, the planimeter or the balance, the correct process is to read the indication either as closely as the importance of the work in hand requires or else to the finest degree possible, regardless of what percentage of error the instrument itself may have. Then in the computation of results from these observations it is also entirely proper to use a number of places of decimals suited to the degree of accuracy it is desired to finally obtain.

It comes about, therefore, very naturally, that engineers in writing reports should set down the figures used in computation, decimals and all; and we doubt not that very few of those who habitually do this have ever had a thought of the effect which this must have upon the mind of an outsider, and which we have explained above. On the other hand, many engineers, especially those who are in close touch with commercial and practical life, have, we are sure, seen the wisdom of eliminating from their work when putting it into shape for final record all of this that we have designated as fictitious accuracy. We notice, for example, in one report of a steel test coming from the laboratory of a large steel works that 250 lbs. is the smallest variation used in giving elastic limits. We note this only as a single example; but an examination of the reports and papers of the best and ablest engineers will show, we believe, that as a rule they use common sense in laying their work before the public, and avoid encumbering it with what is properly only mechanism of computation. We trust their example may be followed by other members of the profession. It is to be hoped also that the professors in the engineering schools may turn their attention to this matter and see to it that their pupils properly understand it. The secretaries of engineering societies, too, can aid in the reform by properly editing the papers presented; but the strongest incentive toward a change should be felt by the practicing engineer. If each man would try to put himself in the place of his client and consider how the practical hard-headed business man will look upon strings of decimals carried out to three or four places, we are sure all fictitious accuracy would disappear from engineers' reports.

LETTERS TO THE EDITOR.

A Question of Professional Ethics.

Sir: I would like to have an opinion on a question of engineering ethics. The Engineer of our Department of Parks has accepted the position of Chief Engineer of an electric railway company organized to run through the park, while still retaining the first-mentioned position. Is this in strict accordance with the ethics of the profession? I would like some information on this point, and think that an opinion would be of great value to young and inexperienced engineers. Will you kindly submit this matter to the profession for its verdict.

Very respectfully, E. K.

July 21, 1896.

The Spread of Dry-Rot.

Sir: In reference to the letter of A. F. W. in your issue of July 23, the result of my experience may be of value. I have frequently had occasion to observe the effect of dry-rot on timbers, and as a general thing find that the hard pines, if affected at all, are only affected to a small degree when properly ventilated. This is, however, not at all true of the softer pines. Cases have come under my notice where softer pines butted against the side of yellow pine have rotted over one-third the area at the end and extending some feet into the interior of the piece, while the hard wood was not affected at all. I have several times had to remove the large white pine timbers from a structure for this very cause, though it was not necessary to touch the yellow pine or oak. In one case in particular I was informed that the timbers had not been disturbed for. 60 years. Oscar Lowinson.

39 and 41 Cortlandt St., New York city, July 25, 1896.

Low Charges for Engineering Work Again.

Sir: Referring to the letter headed "Low Charges for Engineering Work," in your issue of July 16: The writer of that letter did not include the whole of the proposition of the engineer: The proposition was also for "furnishing all legal advice free of charge up to the time of the completion of the plans and specifications and advertising for bids."

This city had the preliminary surveys made in the winter by a firm from a city in New York. The "engineers" were related in some way to one of the councilmen, and made these surveys for the sum of $200, paying their own expenses to and from the work, several hundred miles, and while engaged in making said surveys. Their "bid" for the designing of the plant was $400, but it was found out that they were related to men in official position and their figure was not considered. This firm made an estimate of the cost of the system and it was $50,000 less than that of the present engineer.

Your comment on the letter is timely, in that it shows that the cheap engineer is not always among the so-called "outsiders" (that is, those not members of the engineering societies).

The writer has been asked to join the Am. Soc. C. E. on several different occasions. From what he has seen he is of the opinion that it is not to his advantage in any manner. There is no code of "professional ethics," nor is business courtesy shown among those whom he has met (with two exceptions). The members are for the almighty dollar and work for it in the same manner and use the same means as those outside; one or two of the new members joined with the expressed determination of making trouble for some of the older members. True there is much to be gained from the Transactions of the society, but any energetic man may purchase literature on any of the subjects handled and study the subject for himself.

Yours truly, F. L.

July 18, 1896.

A Possible Solution of the Problem of Weights and Measures.

Sir: The paradox of the day is the contrast between ubiquitous resolutions in favor of the metric system, even from bodies of the most practical men, and the complete absence of its use in actual industry. The explanation is obvious, however. The cost of transferring our tremendous industrial system from our present measures to the metric system would be incalculable. Every machine, tool, pattern, template, and drawing becomes "scrap" immediately upon its adoption. Every atom of accumulated stock, from a wood-screw to a locomotive, becomes an odd size, no longer to be matched or repaired without a resurrection of obsolete tools.

The only requisites of a perfect system of measures are (I.) that they shall be consistent; i. e., all based upon the standard unit of length, and (II.) that the ratio between various units shall always be the same and be the base of the system of notation, which at present is ten. There is nothing sacred or scientific about the metric system except that it fulfils these conditions.

A certain coincidence, viewed in connection with these requirements, becomes of great significance. In the first place, a very common ratio in our otherwise chaotic system of measures is twelve; dozen and gross, foot and inch, year and month, day and hour, shilling and pence, are all such necessary tools for daily life that every child is taught its multiplication tables as high as twelve, instead of stopping at ten.

In the next place there has long been a wide dissatisfaction with our decimal system of notation, and agitation for the substitution of a duodecimal system. In other words, ever since man has counted on his fingers, we have used tens, ten × tens (hundreds), and ten × ten × tens (thousands), etc., with which to count. It is proposed, as incomparably more convenient, to count by twelve, twelve × twelves, twelve × twelve × twelves, etc. To do this we should need twelve digits instead of ten; say, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, φ, and ‖. φ and ‖ being "ten" and "eleven." Thus, in the new system, 2375, for instance. instead of meaning 2 ten × ten × tens, plus 3 ten × tens, plus 7 tens, plus 5 units, would mean 2 twelve × twelve × twelves, plus 3 twelve × twelves, plus 7 twelves, plus 5 units; which is expressed in the decimal system by (3977).* Without attempting a comparison of the two systems the following lists of fractions, those in most common hourly use in the shop, will illustrate the main argument for duodecimals:

Vulgar fraction.	Decimal equivalent.	Duodecimal equivalent.
½	0.5	0.6
⅓	0.333333 (indeterm.)	0.4
¼	0.25	0.3
1-6	0.166666 (indeterm.)	0.2
1-8	0.125	0.16
1-12	0.83333 (indeterm).	0.1
1-16	0.0625	0.09
1-32	0.03125	0.046
1-64	0.015625	0.023

It is therefore proposed that the English-speaking races, who have more money invested on the basis of the two-foot rule than have all the rest of the world on the meter, adopt the much more scientific duodecimal system of numbers, found a duodecimal system of weights and measures on the standard yard at Washington (which is just as good as the standard meter at Sevres), reprint their arithmetics, and keep their two-foot rule in their pockets. To illustrate:

For linear measure, the units would be the yard, the 1,000-yard (in decimal numbers 1,728 yds. = 5,184 ft., or so nearly a mile that off-hand conceptions of distance would not have to be altered), the 0.1-yard (= 1-12 yard = 3 ins.), the 0.01-yard (= ¼-in.), and for minute measurements the 0.001-yard (D = 1-48-in.). Thus, a drill-rack, without any alteration in the tools themselves, would be re-labeled as follows:

Present mark, in inches.......(1″)	($\frac{3}{4}$″)	($\frac{5}{8}$)	($\frac{9}{16}$)	($\frac{17}{32}$)	($\frac{1}{2}$)	($\frac{15}{32}$)	($\frac{7}{16}$)	($\frac{3}{8}$)	($\frac{1}{4}$)	($\frac{1}{8}$)	($\frac{1}{16}$)	($\frac{1}{32}$)	($\frac{27}{64}$)	($\frac{43}{64}$)	etc.
New mark, in 0.01-yds......... 4	3	2.6	2.3	2.16	2	1.φ6	1.9	1.6	0.1	0.6	0.3	0.16	1.83	2.83	
Or, in 0.001-yds...............40	30	26	23	21.6	20	1φ.6	19	16	10	6	3	1.6	18.3	28.3	

Although this may seem confusing at first, the more it is studied the more it will be liked.

For surface measure the units should be the square yard and its duodecimal fractions: The 0.01-sq. yd. (= 3-ins. square), and the 0.0001-sq. yd. (=¼-in. square). For land measure the acre would be replaced by the 10,000-sq. yd., a square 100 (144) yds. long, on a side, and amounting to 6.1% more than four acres; 100 (144) of these land-measure units equal one (new or duodecimal) square mile.

For measures of volume, the cubes of the linear dimensions are convenient. Thus, the cube of 0.1-yd. = 0.001-cu. yd., has a volume not far from one pint, or 3-7 of a liter. One cu. ft., for instance, equals 54 (64) such cubes. The complete lack of consistency in our present bulk-measure renders this application of the new system the most independent of any.

For weight the unit should be the weight of one "cube" of distilled water at maximum density. This would be within 2½% of 1 lb. avoirdupois, or very convenient for off-hand estimates, and might be called a "poid." The short ton would be replaced by the 1,000-poid, a weight about one-sixth smaller, or about ⅝-tonneau metric. 0.1-poid equals about 1⅓-oz. 0.001-poid is nearly equivalent to 4 grains or ¼-gram metric.

For time the table would run: 50 secs. = 1 min., 50 mins. = 1 hr., 20 hrs. = 1 day, 265.3 days = 1 year, 10 months = 1 year.

When the reform of our system of measures is undertaken, let it be done scientifically and finally for all time. This will not be unless the new system be based on duodecimals. It is easier, and vastly cheaper, to reprint our mathematical books than to refurnish our factories and restock our warehouses. Yours truly,

Sidney A. Reeve.

Worcester Polytechnic Institute, Worcester, Mass., July 14, 1896.

---

*To avoid confusion, numbers in the decimal system will be surrounded by parenthesis; those in the duodecimal system are printed free. If this be forgotton the letter becomes meaningless.

The Benefits of Dry and Superheated Steam.

Sir: Your editorial article on "The Efficiency of Steam Boilers," in your issue of June 11, together with several other articles that appeared about the same time in other journals upon this and the kindred subject of superheated steam, lead me to offer the following upon the general subject, as the results of years of observation.

1. The quality of the steam furnished by a boiler (whether wet, dry or superheated) is a factor that enters more largely into the question of efficiency than is generally understood.

2. The importance of this factor will depend largely upon the use that is made of the steam and, therefore, a statement of efficiency based simply upon the number of heat units transferred from the coal to the water may be misleading.

3. The commercial efficiency of the boiler will depend upon the amount of coal required to do a given amount of the work required of the boiler.

4. If the steam is used to supply heating coils or jacket pans, or in boiling dye-stuff, the importance of the quality of the steam will be at the minimum. For, suppose three boilers, each of which is imparting 9,660 units of heat to the water per pound of coal, it will make no material difference in this case whether No. 1 shows 3% of moisture, No. 2 makes dry steam, or No. 3 superheats 20°, for during condensation to atmospheric pressure, the same number of heat units will be surrendered by each per pound of coal used.

It is true that even for such use dry or superheated steam has the advantage of an increased efficiency of apparatus due to drier surfaces and more free circulation, but the cost of doing the work will be practically the same, and the usual statement of efficiency (66%) will be correct.

5. If, however, the steam is used in a steam engine to generate power, differences of great moment will be observed. In such cases, which are far more frequent than the other, the loss of heat in the exhaust leaves but a small percentage available in the engine, and of this small proportion which should appear in useful work, a large part is lost in condensation in the cylinder, etc. With wet steam these losses are increased and with superheated steam they are largely decreased.

Numerous experiments are recorded which show a saving of 25% and upwards by the use of superheated steam (see Prof. Thurston's recent paper before the American Society of Mechanical Engineers), and while much has been written on the subject, no satisfactory explanation has been given, either of the cause of cylinder losses, or of the saving due to superheating.

I have given this subject considerable thought and have some experience and records which I may submit in the future as to the cause of cylinder losses, but for the present will only venture to give a reason(?) for the gain by superheating steam, as it bears directly upon the question of boiler efficiency.

Dry steam at 100 lbs. (gage) pressure, carries 1,184 units of heat per pound.

Steam at the same pressure superheated 20°, carries 1245. heat units per pound.*

Assuming feed water at 212° (in the boilers Nos. 2 and 3 referred to in paragraph 4), we would have for No. 2, 1184.—180=1004.; and for No. 3, 1245. — 180 = 1065, units of heat imparted (from the coal) to each pound of water, and an evaporation of 9660.÷1004.=9.62 lbs. of water per lb. of coal for boiler No. 2, and 9660. ÷ 1065. = 9.02 lbs. for boiler No. 3, or 6% more steam (in weight), from No. 2 than from No. 3. The initial volume of the steam would however be nearly the same, but we propose to neglect this item as inconsiderable.

If this steam is used in heating coils, the entire storage of heat (above 212°) is surrendered for useful work and no material economy of fuel is realized.

If the steam in either case is used in a non-condensing engine and expanded to atmosphere, it will still contain an average of 1,050 h. u. per lb. when exhausted, 180 of these units may be returned to the boiler in the feed water, which leaves 870 h. u. necessarily wasted out of each pound of either dry or superheated steam used. The amount of heat surrendered for use in the engine by each pound of the dry steam is, therefore, 1004. — 870 = 134 units; from the superheated steam it will be, 1065. — 870 = 185, showing an excess of 51 units or 38% more of available heat in each pound of the superheated steam. To be more exact we have 134 × 9.62 = 1289. units per pound of coal available through the dry steam and 185 × 9.06 = 1676. through the superheated steam, an excess of 30%.

The cylinder losses will be practically the same with each kind of steam, as will be seen from the subjoined analysis of Mr. Dixwell's experiment, and the result will be an economy of 30% or less by using the superheated steam, the entire credit for which should be given to the boiler.

We have reached the point where the value of superheated steam is well understood by our best engineers, though the cause of its superior efficiency may be still considered in doubt, and a real service will be done the art if a revision of our methods of determining boiler efficiency can be had.

Steam jackets are valuable for the same reason given above, i. e., they increase the available heat in the steam they use, but their value is largely destroyed by the moisture laden product of many of the boilers in use of late years. Jackets may be dispensed with if the steam is moderately superheated.

Compound and triple expansion engines require less of superheat in the initial steam than do single cylinders, the range of temperature being comparatively small, it is easy to deliver dry steam to the receiver, which, if properly jacketed with boiler steam, will superheat the steam for the lower cylinder and thus prevent condensation through the entire range of expansion.

The steam condensed in the receiver jacket surrenders 1245. — 308 = 937 units per pound, which if it is used to superheat dry steam, is all available in the low pressure cylinder; but if the steam comes to the receiver wet and the jacket serves only to re-evaporate entrained water, it will be of little value, for of the 937 units imparted, 870 will be lost in the exhaust, and it would be as well to send the extra steam through the cylinders.

Using a boiler that has 15 to 20% of its heating surfaces in the steam space and that makes uniformly superheated steam, but whose efficiency is not particularly high (as ordinarily expressed), I am able to predict and realize a large saving of fuel, and being properly designed with reference to the circulation of water and the proper cooling of the gases before reaching the superheating surfaces, this type of boiler is quite as durable as any other. Twenty years of personal experience in the use of superheating boilers justifies this statement

The test of a Corliss engine in the Institute of Technology of Massachusetts, made by Mr. George B. Dixwell (Proceedings of the Society of Arts, M. I. T., 1887, 1888), under the supervision of C. H. Loring, Chief Engineer U. S. N., and a board of naval experts, give the most complete data upon this interesting subject. The engine was run non-condensing and a calorimeter was used to measure accurately the amount of exhaust and the heat contained in it. The accompanying table shows the results:

Results of Tests to Determine Economy due to Superheating

No. of test.	Kind of steam used.	Pressure by gage.	Deg's of superheat.	Duration of experiment (mins.)	Point of cut-off.	H.P. Developed.	Water per H.P. developed.	Heat units in the exhaust.	Per cent of gain.
1.	Saturated	...50.4	....	137	.217	7.65	48.2	1046.	..
2.	"	...50.2	....	83	.443	12.7	42.2	1084.5	..
3.	"	...50.3	....	63	.689	15.68	45.3	1101.4	..
4.	Superheated	50.4	179°	180	.218	6.83	35.2	1138.6	27%
5.	"	50.	142°	108	.439	12.37	31.7	*1159.4	25%
6.	"	50.2	107°	75	.672	15.63	35.8	*1170.8	21%

*In experiments 5 and 6 the thermometer showed no sensible superheat in the exhaust steam. Steam at atmosphere superheated 1° or less (by thermometer), carries 29.3 units in excess of saturated steam.

The most economical use is made of superheated steam when the exhaust carries about 1,100 units of heat, for in such a case the adiabatic condensation is available and no water accumulates in the cylinder.

---

*The total heat of superheated steam is found by the formula ($H = 1074.6 + .48\ T$), in which T is the observed temperature of the steam. This formula was constructed by Prof. Rankine and its correctness theoretically demonstrated. Later experimental evidences also confirm it, Mr. D. K. Clark confirms it and the experiments of Mr. Dixwell which are here cited most clearly demonstrate it. The Dixwell experiment also shows that the provisional formula, $H = H_1 + .48\ (T - T_1)$ which is used by some engineers is certainly wrong, for in this formula H_1 is the total heat of saturated steam at the observed pressure, T_1 is its temperature and T the observed temperature of the superheated steam, and if we apply it to experiment No. 6 we find the total heat to be, $1172.7 + .48\ (406 - 298) = 1224.5$, from which take the heat found in the exhaust, (1170.8) and we have 53.7 units used in the engine per pound of steam, and since 35.8 lbs. were used per horse power per hour, we get, (53.7×35.8) equals 1922.4 h. u. per hour, or 32 h. u. per minute, used to generate 33,000 ft.-lbs., whereas we know that 42.7 are necessary. In short, if this formula is correct, this engine was delivering (in power and to the exhaust) more heat than it was receiving from the boiler, which is of course absurd.

It is, therefore, apparent from Mr. Dixwell's table, that in all the experiments with superheated steam the point of cut-off was too late to use the steam to the best advantage, especially so in Nos. 5 and 6, where the exhaust was superheated 12 and 24 units respectively. The decrease in the per cent. of savings was due to this cause, and if the point of cut-off had been properly adjusted in each case, the saving would have been greater and the per centage more even. Of course this could only be done by sacrificing power.

The advantage in using superheated steam lies entirely in the fact, that it carries a larger proportion of available heat and may surrender what is required to maintain the heat in the pipes and cylinder without losing its elasticity.

The accompanying analysis of Mr. Dixwell's experiment is given to show more clearly how the small number of extra heat units in the superheated steam (as compared to the total), becomes of so great importance when compared to the available heat.

Analysis of Mr. Dixwell's Experiments.

Number of experiment	1	4	2	5	3	6
Power developed, HP	7.65	6.83	12.7	12.37	15.68	15.63
Quality of steam	Saturated	Superheated	Saturated	Superheated	Saturated	Superheated

Temperature of steam	298.°	478.°	298.°	441.°	298.°	406.°
*Total heat in live steam, per lb., B. T. U.	1172.77	1304.	1172.77	1286.28	1172.77	1279.4
Total heat in exhaust steam, per lb. “	1046.	1138.6	1084.5	1159.4	1101.4	1170.8
Consumed in engine per lb. of steam “	126.7	165.4	88.2	126.0	71.3	108.6
Steam used per HP. per hour, lbs	48.2	35.2	42.2	31.7	45.3	35.8
Heat consumed per hour per HP., B. T. U.	6106.9	5822.	3724.9	4019.56	3229.9	3887.
Heat consumed per minute per HP. “	101.2	97.	62.	66.8	53.8	64.7
Equivalent energy in ft.-lbs., per minute	77972.	74884.	47864.	51569.	41533.	49938.
Converted into power ft.-lbs. per minute	33000.	33000.	33000.	33000.	33000.	33000.
Lost from cylinder condensation, etc., ft.-lbs.	44972.	41884.	14864.	18569.	8533.	16938.
Per cent. of waste in cylinder	55.%	53.%	31.%	36.%	20.%	33.%
Steam saved per HP. per hour, lbs	....	13.	...	10.5	...	9.5
Per cent. of saving	....	27.	...	25.%	...	21.%

*The total heat of the superheated steam is found by the formula of D. K. Clark: $H = 1074.6 + .48\,T$, in which T is the temperature of the steam.

Comparing Nos. 1 and 4, we find that the heat consumed per minute, per horse power, was practically the same, and that the losses in the cylinder were also very nearly the same with each kind of steam and that the actual saving was in proportion to the amount of heat consumed per pound of steam used. (A confirmation of the correctness of the formula $H = 1074.6 + .48\,T$.

It follows clearly, from the foregoing, that of the heat applied to the water surfaces of a boiler to generate steam not more than 12% can be used in the engine (single cylinder, non-condensing), and that ALL the heat imparted to the steam after it is generated can be used in the engine, and that therefore a heat unit in superheat is eight times as valuable in an engine as a heat unit in dry steam.

It is also clear that it does not pay to superheat beyond what is required to prevent condensation in the cylinder; and finally that of two boilers having the same apparent efficiency, the one that furnishes moderately superheated steam will be far superior to the other if it furnish simply dry steam.

Wm. H. Berry, Consulting Engineer.

Chester, Pa., June 24, 1896.

Notes and Queries.

The present address is desired of Mr. F. D. Lyphart, C. E., lately at 15 East 7th St., Cincinnati.

THE LEGAL DUTIES OF ENGINEERS AND ARCHITECTS.*

It would be difficult to exaggerate the importance of the duties and functions of architects and engineers. In the practice of their professions, technical skill and learning, good judgment and honesty are necessarily required. No science, that I know of, is more difficult to master, or requires, in practice, a higher order of ability, than those of architecture and civil engineering.

If a man holds himself out to the world as an architect, he is presumed to be qualified in every proper sense. His client necessarily relies on his skill. If, therefore, he should be wanting in skill, and, in consequence, his client suffers injury, he would be liable. The relation between the architect and his employer is similar to that of lawyer and client, or of physician and patient. The professional man who is employed, as such, by another, must bring to the task he has engaged to execute, all the skill and learning necessary to do it. It would be a gross fraud and great injustice to permit an architect or engineer, who had been employed by another, confiding in his skill, to escape the consequences of his own ignorance and unskilfulness. The rule rests upon the broadest principles of equity.

Besides learning and skill, an essential quality in an architect or engineer is honesty. The law requires the observance of the utmost good faith on the part of the architect to his client. An unfaithful architect could easily bring upon his client ruin and disaster, without the ability on the part of the latter to avert it. One of the commonest rules of the law of principle and agent is, that a man shall not serve two masters. It has sometimes happened that architects and engineers have undertaken to serve the man who employed them to design and supentend the construction, and at the same time have taken a fee from the contractor. Such conduct is reprehensible, both in morals and in law. One of the consequences of the violation of this rule is, that the architect is not permitted to claim compensation for his services, however meritorious, from either party. The law forfeits his compensation as a just penalty for his unfaithfulness.

An architect, while bound to observe the best faith to his employer, the builder, is bound to treat the contractor fairly. He cannot exercise his power so as to wrong or defraud the contractor. Thus, where, by the building contract, the architect or engineer is made the arbitrator of differences between the proprietor and the contractor, his position is that of a judge, bound to act with impartiality; and if he should make an agreement with the proprietor to give him the advantage in his decision, such agreement would be illegal, and his decision or award would be void. Where the architect is made an arbitrator, he ceases to be the agent of either party, and his decision must be made in a spirit of fairness, and without regard to his former relations.

Where the architect or engineer is employed by the proprietor or projector to superintend a proposed work, the relation of principal and agent is established. It oftentimes becomes a matter of importance to define the limits of the agent's authority and to what extent he may bind his principal.

The general rule is, that in the absence of stipulations to the contrary the authority of the architect will be determined by the character of the work, and the objects intended to be accomplished.

One limitation upon the power of an architect or engineer seems to be without exception. Where it is not expressly permitted, he cannot delegate his authority to another. The position of an architect or engineer is one involving special trust and confidence in his skill and honesty, and if he were permitted to assign his duties or substitute another in his place, injustice and wrong would often be done his employer.

An architect transcending his authority makes himself personally liable to the contractor. He is presumed to know the extent of his powers better than the contractor, and if the latter does work at the instance of the architect, which he had no authority to order, he will be personally liable.

It becomes the duty of the architect and engineer, during the progress of the work, to issue to the contractor what are known as progress certificates, and, when the work is completed, to issue final certificates. These certificates are evidences to the owner of the progress of the work and of the right of the contractor of payment. Most contracts provide that payment shall be made only on the certificate of the architect or engineer, and the issuance of the certificate thus becomes a condition precedent to payment. The certificate, when issued, is binding on both the owner and the contractor, and unless it can be shown that the architect acted fraudulently or corruptly neither party can complain. The decisions have gone to the extent that, where the certificate is made a condition precedent to payment, the contractor cannot maintain a suit unless he produces a certificate. Of course, where the certificate is corruptly and unreasonably withheld, the contractor may, upon averring that fact, bring suit. And the architect may make himself personally liable by capriciously and wrongfully withholding the certificate.

A usual stipulation in contracts is that the work shall be completed on or before a certain time. Accompanying the stipulation as to time there is usually, and ought to be, a stipulation subjecting the contractor to the payment of a certain sum as liquidated damages, in case of failure. Such provisions are wise, because they act as a spur on the contractor. The propriety of fixing an amount as liquidated damages in case of default is apparent, when you remember that unless the damages are agreed on, they can hardly be settled without litigation. Where a certain amount is agreed on in the contract as liquidated damages, there is no room for controversy. Such provisions have been uniformly sustained by the courts.

Where the contract is silent as to the time of performance, the law infers that a reasonable time is meant.

The stipulation as to time in a contract may be extended or waived, and such waiver or extension may be in parol—that is, not in writing.

It is a general rule that a building contract cannot be specifically enforced; that is to say, the contractor cannot be compelled, against his will, to perform or complete, nor can the other party be required to permit the contractor to do the work. If the parties choose to disregard the contract, they may do so, but at the risk of being called upon to pay damages.

The question that has given architects most trouble, and occasioned most controversy and litigation, is extras. It is a common saying that a house usually costs double the contract price, because of extras. Dearly bought experience has caused the insertion in most building contracts of special stipulations to avoid them. The usual provision is, that no alterations or additions shall be made without the consent of the owner. Sometimes it is provided that the consent shall be in writing. The architects are sometimes hedged about with very stringent restrictions; a common provision is that no addition or extra shall be made or allowed by the architect. When he is authorized to do so, it is usually provided that the architect shall agree to it in writing. The owner may, of course, waive the stipulation forbidding extras, and he may do it as he pleases, either in parol or in writing. But the architect has no such authority, except with the consent of the owner. If he should waive it, the owner would not be liable for the extras, and the architect might be liable in damages to the contractor, for authorizing them.

The builder is bound to scrupulously follow the specifications, and cannot justify a departure therefrom by substituting other details, although as good as those called for. He is as firmly bound by the terms of the specifications, as by the covenants of the contract—for they are, in fact, a part of the contract. Nor can the architect change them, except by special authority from the owner. Where there is obscurity in the drawings and specifications, the contractor must apply to the architect for directions, or he undertakes the work at his own peril.

Where, however, the work has been performed in full compliance with the specifications, no responsibility will attach to the builder if the structure falls, or is practically worthless owing to defectiveness and insufficiency of the plans and specifications. It is the contractor's duty faithfully to execute the work for which he has been engaged, and he is not responsible if the undertaking is valueless, nor is he liable for any defect in the building caused by defectiveness in the plans furnished him by the owner. So far as the plans are adopted by the owner, they become his, and he is responsible for claims accruing to the contractor or others for defect in the plans.

I have diverted to the question of damages. It may not be improper to note a distinction on this subject which, perhaps, is not known to all of you. Although the parties to the contract have a perfect right to determine, beforehand, what shall be the damages which shall be paid to the other by the one who violates it, the law does not enforce such agreements when they amount to the imposition of a penalty or forfeiture. Where the amount stated to be paid for a breach of the contract is evidently what the parties assess as the damage caused thereby, the stipulation will be upheld as liquidated damages; but where the object is to secure its performance by the imposition of an amount in excess of the loss likely to be sustained, it will be considered a penalty, and will not be enforced.

The distinction between liquidated damages and penalties attached to contracts for the breach of same, is not always easily drawn. The following rules have been deduced from the decisions of the courts on that question, viz.:

Where the sum fixed as liquidated damages is manifestly above the injury sustained, it will be held to be a penalty, and only actual damage can be recovered.

Where the contract is for a matter of uncertain value, and a sum is fixed to be paid on the breach of it, the sum is recoverable as liquidated damages.

Where the payment of the money appears to have been intended only to secure the performance of the contract, it will be construed as a penalty.

Where a contract contains a number of conditions, and the penalty is applied to only one of them, it is not recoverable as liquidated damages.

Forfeitures are abhorred, especially in courts of equity, and will not be enforced. The object of the courts is to make the parties whole, and where that is accomplished the ends of justice have been met. Hence, it is difficult, in any case, to recover, upon a breach of the contract, more than the parties have been actually damaged.

It is frequently the case—indeed, it may be stated that it is generally so—that security is required of a contractor for the faithful performance of the work. The general rules of law relating to suretyship appertain to cases arising under building contracts. Where a surety guarantees that the builder will execute his contract to the satisfaction of the employer, and the contract is materially altered without the surety's consent, he will be discharged, whether the change or variation in the contract is prejudicial to him or not. The reason is that a new contract has been entered into without his consent. The same thing is true if the time of performance is increased without his consent.

---

*Condensed from an address delivered before the Engineering Association of the South by Hon. Jas. C. Bradford, Nashville, Tenn.

Where, by a contract, the surety guarantees the performance of the building agreement, which was to be paid for in installments, and the owner paid the installments before they were due, it was held that this act discharged the surety. So also, where the owner failed to insure the property, as agreed. So also, where he made larger advances to the builder than contracted for.

It may be stated, as a general rule, that the surety is discharged whenever the owner and the builder change, in any respects, the terms of the contract. It is, therefore, important that the contract should always be strictly followed and observed, and an architect or engineer should be scrupulously exact in his construction of contracts and in the enforcement of their execution; because, as the agent of the owner, he may, by some act on his part, discharge the surety and thus materially damage his principal.

Of course many intricate questions must necessarily arise which it would be impossible for an architect or engineer to decide. Even the application of old and well-settled principles becomes frequently very difficult. In such cases, the best advice I can give you is that you should advise your clients to apply to another worthy class of professional men for advice, viz., the lawyers.

In conclusion I beg to add a few words upon the character of your professions, and the necessity of promoting and maintaining a high standard of education and ethics. The arts of architecture and engineering have been associated with some of the noblest achievements of the human race. In both we find the evidences of man's progress from a savage condition to a high state of civilization and culture. Like the other arts, architecture did not spring into existence at an early period of man's history. The idea of symmetry and proportion, which were afterwards embodied in material structures, could not be evolved until at least a moderate degree of civilization had been attained, while the efforts of primitive man in the construction of dwellings must have been at first determined solely by his physical wants. Only after these had been provided for, and materials amassed on which his imagination might exercise itself, would he begin to plan and erect structures possessing not only utility but also grandeur and beauty.

It is only by a thorough study of the history and the techniques of their arts that the architect and engineer can achieve rank and distinction, or even such knowledge and skill as will enable them to perform successfully the ordinary calls that are made upon them. Thorough training is not only important to the architect himself, but to the public as well.

No less important than knowledge and skill is a high standard of morals. Every profession ought to have an ethical code of a high order for its government. I doubt not that with you it is so.

THE ADOPTED PLANS FOR THE NEW EAST RIVER BRIDGE.

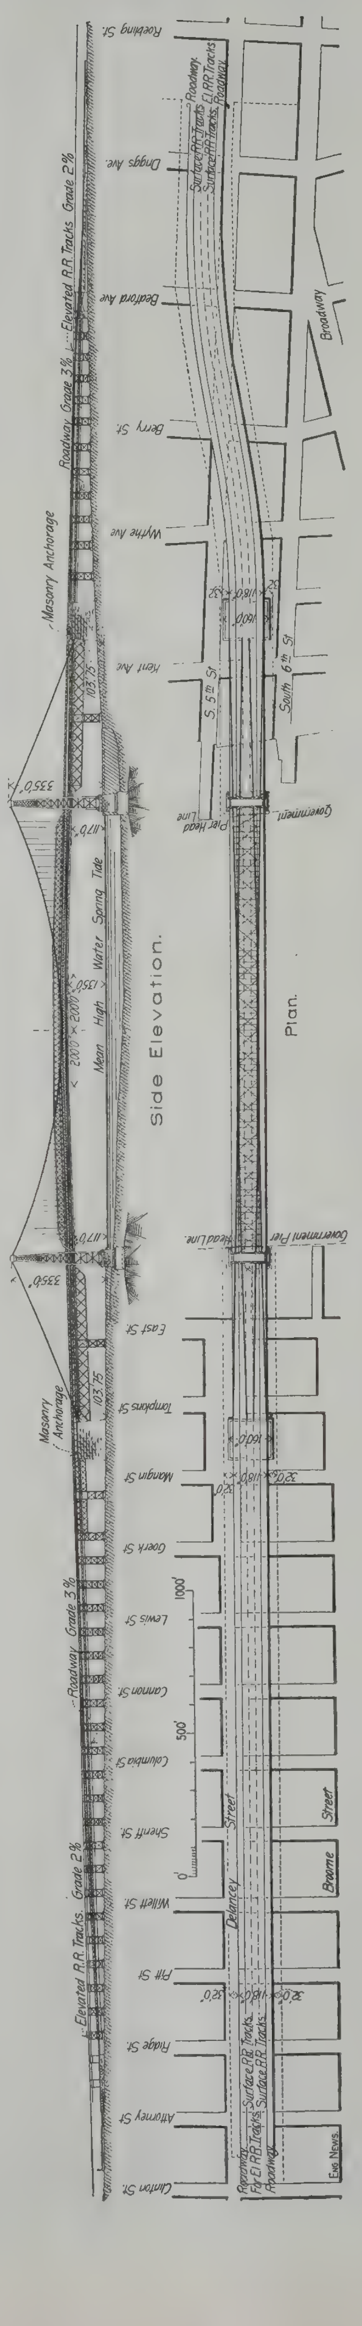
We show in the accompanying drawings a plan, elevation and sections of the new East River Bridge, which have just been officially adopted by the Commission in charge of the work. It is, perhaps, not generally realized that this bridge will have the longest span of any bridge in the world save the Forth Bridge. It will be the longest suspension bridge in the world, exceeding the present East River Bridge, however, by only 4 ft. 6 ins. The new East River Bridge will be 1,600 ft. from centre to centre of towers. The present bridge is 1,595 ft. 6 ins. measured from the same points. The other principal dimensions of the new structure will be as follows:

Length of entire bridge, between terminals	7,200 ft.
Width of bridge, outside to outside of carriageways	118 "
Minimum height of bridge above mean high water of spring tides at pier-head lines	117 "
Minimum height of bridge above mean high water of spring tides for 200 ft. on each side of centre of main span	135 "
Height of masonry in tower foundation above high water	20 "
Height of centre of cables at top of towers above high water	335 "
Width of carriageways, each	18 "
Width of 2 footwalks, each	12 "
Width of 4 trolley car tracks, centre to centre	10 "
Width of 2 elevated railroad tracks, c. to c.	12 "
Two stiffening trusses between towers, distance apart from centre to centre	72 "
Grade of approaches	3%
Grade of elevated railroad tracks	2%

The new structure will have towers of masonry from the foundation to a point 20 ft. above high-water. The towers above this point and the entire suspended structure, except the flooring, will be of steel. The cables will be of straight steel wires, No. 6 B. W. G. The shore spans and approach viaducts from the end of the suspended structure to Bedford Ave., in Brooklyn, and to Ridge St., in New York, will be of steel, and the remainder of the viaduct approaches will be of masonry.

The cables are to be four in number, and 17½ ins. in diameter, each made up of 19 strands. The borings thus far made show that rock foundations will be found at from 70 to 100 ft. below high-water mark. The total height of the towers above high-water mark will be 336 ft.

As most of our readers will remember, Mr. L. L. Buck, M. Am. Soc. C. E., is the Engineer-in-Charge of the work and Mr. O. F. Nichols, M. Am. Soc. C. E., is his principal assistant. The Commission under whose authority the work is being carried on consists of Col. Andrew D. Baird, Salem H. Wales, F. B. Thurber, Richard Deeves, Henry Batterman and James H. Sperry, with Mayor William L. Strong, of New York, and Mayor Frederick W. Wurster, of Brooklyn, as ex-officio members.



THE ADOPTED PLANS FOR THE NEW EAST RIVER BRIDGE.

Leffert L. Buck, M. Am. Soc. C. E., Chief Engineer, Othniel F. Nichols, M. Am. Soc. C. E., Principal Assistant Engineer.

FLOWAGE TEST OF A 14-IN. RIVETED STEEL MAIN AT NEW WESTMINSTER, B. C.

By A. McL. Hawks.

The following excerpt from a report to the City Council of New Westminster, B. C., upon the test of the 14-in. riveted steel supply main forming a part of the water-works system of that city may be useful in view of the small amount of information available regarding the actual delivery of steel mains.

Before giving the results of the test a short description of the main itself will be necessary for a thorough understanding of the subject. The water supply to the city of New Westminster was constructed in 1892, under the direction of Mr. Arthur Hill, M. Inst. C. E., chief engineer. The headworks on the Coquitlam River are simply a perforated length of pipe laid in the bed of the river; about 300 ft. of pipe leads into a cast-iron circular well or gate chamber in which are situated the screens; thence the supply main extends for 70,700 ft. to a reservoir on the hill above the city. The top of the supply main at the screen chamber is at elevation 424.8 ft. (city datum); the bottom of the reservior is at elevation 385 ft.

The supply main is of soft steel, 14 ins. clear diameter of the smaller ring, with double riveted longitudinal seams and single riveted circumferential seams. The double riveting is spaced about ¾-in. between rows, 1 in. between heads, and staggered. The circumferential rivets are ¾-in. c. to c. upon the exterior surface, or about ½ on the interior surface, varying slightly with the gage of steel, which runs from No. 9 to No. 12. All rivet heads are circular or "snap heads," and as the rivets are of ¼-in. diameter the heads form almost a complete ring upon the interior of the pipe and practically reduce the clear opening about ¼-in. Seven rings of steel plate, four of the greater and three of the lesser diameter, formed a length of pipe of 24 ft., as made up in the shop. One end was reinforced by a welded steel plate ring 5 ins. wide and 14 ins. clear diameter, the end lengths of the pipe being of the greater diameter and the rivets near the outer ends being practically countersunk. In making up the pipe the longitudinal seams were "in line" in alternate rings and quartering one another in adjoining rings. All lengths were dipped and very thoroughly coated in an asphaltum bath; and all were thoroughly tested before leaving the shop.

The mode of laying was as follows: The pipe was placed in the trench with the longitudinal seams underneath, forming angles of 45° with the vertical plane; the reinforcing ring in the end of one length, which projected about half its width from the pipe length, would be forced into the next until the pipes were practically in contact; an exterior, welded ring of heavy plate about ⅝-in. thick and 5 ins. wide, which had previously been slipped over one end, would be pushed forward to cover the joint; and a calked lead joint would complete the laying.

From the foregoing it will be seen that the obstructions to flow through the pipe would consist of: (1) the double line of longitudinal rive heads along the lower quarters of the pipe; (2 the circle of rivets making the transverse joints about 3½ ft. apart; (3) the lap of the outer over the inner ring at these transverse joints; (4) the reinforcing ring at the end joints, 24 ft. apart.

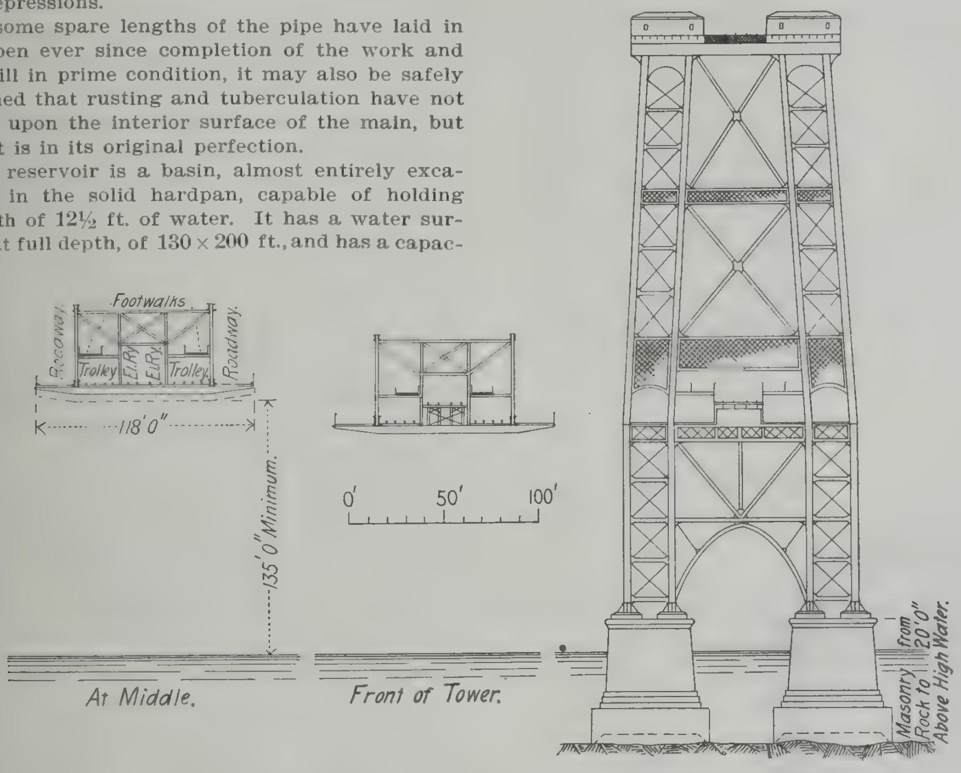
The profile of the pipe line is fairly smooth, long stretches running on benches with easy grades. There are four principal summits and five principal depressions between the intake and the reservoir; two of the summits approach hydraulic grade line, and two of the depressions are at or near zero of the datum plane. In only two places are the changes of grade abrupt. Along the line all the summits are provided with automatic air valves, and all depressions are fitted with blow-off gates.

The alinement is very easy, no quick bends occurring in the whole length. The only places requiring sharp curvature are in streets approaching the reservoir, where the 90° curves are made in six 15° cast-iron pipe lengths. For the above reasons all calculations may be made without any account being taken of friction from bends.

The pipe line is patrolled daily, and all air valves and blow-offs frequently inspected and tested, so it may be assumed that there are no "air spaces" at the summits and no mud deposits in the depressions.

As some spare lengths of the pipe have laid in the open ever since completion of the work and are still in prime condition, it may also be safely assumed that rusting and tuberculation have not set in upon the interior surface of the main, but that it is in its original perfection.

The reservoir is a basin, almost entirely excavated in the solid hardpan, capable of holding a depth of 12½ ft. of water. It has a water surface, at full depth, of 130 × 200 ft., and has a capacity of about 220,000 cu. ft. or 1,725,000 gallons. At a height of 10 ft. is a berm, which is paved with broken rock of small size, as is also the slope from the berm to the bottom of the reservoir; above the berm is a paving of large broken rock laid dry, extending to the top of the bank.



Cross Sections of Span.

Elevation of Tower.

CROSS SECTIONS OF NEW EAST RIVER BRIDGE.

In one corner of the embankment stands a rectangular wrought iron well, 3.1 × 4.2 ft. inside measurement, into which a 14-in. pipe leads from the reservoir; and out of which a 6-in. cast-iron pipe leads to a box drain. A partition divides this well into two compartments, the one on the inflow side (which contains the gage, zero of which coincides with the bottom of the reservoir) being 2.8 × 3.1 ft., and the one on the outflow side being 1.3 × 3.1 ft. At elevation 11½ ft. on the gage is the bottom of a rectangular notch in the partition, which is for the purpose of regulating the overflow of waste water. This notch is in a sheet of No. 8 steel and is 15 ins. wide in the clear. Although not designed for the purpose, it served admirably as a weir over which to measure the whole volume of water delivered by the supply main.

The following regarding the test is extracted from my report to the City Council of New Westminster, dated April 14, 1896:

> On April 2 I visited the intake and headworks on the Coquitlam, going over that portion of the line between the junction and the intake. The depth of water in the screen chamber was taken at 7.98 ft., which would make the surface of water 429.15 ft. above datum. As you will see from calculations given later on, it takes about 24 hours for water to flow from the intake to the reservoir. So I assumed that no considerable variation took place between the hour upon which we observed the height of water on the afternoon of April 2 and the evening of April 3, when we tested the flow. No storms had occurred and no considerable variation of temperature to affect the melting of snow upon the mountains. With the lake and the river near the normal stage, I deem such assumption to have been safe. As a change of 1 ft. would only vary the hydraulic grade by .000,014, and the probable change was 0.1 ft. or less, it may be disregarded.
>
> On the evening of April 3 the actual tests of flow were made. The square notch of plate iron in the overflow well situated at the corner of the reservoir, was used as a weir for the tests. It is admirably suited for such purposes, as it has the prerequisites of being a thin plate with square corners and level along the lower edge; and having a clear opening over three times the head upon the weir; and furthermore the clear outfall is more than half the head of water on the weir; the distance from the side of the weir to the side wall of the chamber is more than equal to the head; and the depth from the lip of the weir to the bottom of the chamber is more than twice the head. All these conditions being fulfilled the "Francis" formula for discharge over thin plates.
>
> $$D=3.36\times(l-1\text{-}5\,h)\times\sqrt{h^3}.$$
>
> l being the length of the weir in feet and h being the head of water over the weir, measured on the gage, was used and the results are derived therefrom.
>
> Preparation was made for the test by drawing the reservoir down until there was about 4 ins. over the weir, which was approximately the least possible discharge which could be expected. The supply to the city was then cut off and the total inflow allowed to waste over the weir. As was expected, the head on the weir increased slowly, but an unexpected factor entered into the problem, which delayed matters for some time. Screens of small mesh wires had been placed over both the inner, or reservoir, and outer, or overflow well ends of the 14-in. cast iron pipe at time of construction. These retarded the flow to such an extent that where little or no difference in level between the surface of water in the reservoir and well had been anticipated there was an actual variation of over 0.08 ft., or about 1 in. The balancing of levels was uncommon and worthy of note. First the water in the well would remain stationary for a few minutes and that in the reservoir would slowly rise; then in the well it would rise ⅛-in. very quickly; again it would remain stationary in the well and rise once more in the reservoir; then in the well rise another ⅛-in.; and this process continued for about two hours. At the end of this time it remained stationary at a depth of 4⅝ ins. for a period of 15 minutes. To determine that this was full depth the weir was closed for ten minutes and the reservoir allowed to fill; then the weir was again allowed to flow freely and the surface of water slowly sank to the former depth.
>
> As the surroundings were so favorable, permission was sought and granted to make another test. Upon the following evening the city supply was again shut off and the full inflow allowed to accumulate in the reservoir. A careful reading with hook gage was taken about ten minutes after the supply to the city was cut off; intermediates were taken by eye on the gage in the well every 15 minutes; and a final hook gage reading made at the end of 2½ hours. The water was then entirely shut off from the reservoir and it was allowed to stand until morning to ascertain if there was any leakage to be allowed for during the tests, the supply to the city being furnished through the 6-in. cut off. No leakage was found, the gage reading the same as when left at night.
>
> The elevation of water as observed at the screen chamber on April 2 was 429.15 ft. above datum; the surface of water in the reservoir on April 3 at the time of the weir test was 396.95 above datum; which would make the grade in your main 32.2 ft., or a hydraulic gradient of 0.000,455, or .455 ft. per 1,000, giving by "Kutter" a velocity of 0.84 ft. per sec.
>
> The reading over the weir was 4⅝ ins., or 0.39 ft., which gives a discharge of 0.96 cu. ft. per sec.
>
> The test by filling the reservoir gives a volume of about 8,900 cu. ft. for a period of 9,000 seconds, or a rate of 0.99 cu. ft. per sec. As these two results agree with less than 3% they may be taken as reasonably accurate.

The raising of the water 0.35 ft. in the reservoir over an area of 25,225 ft., gave a volume of 8,829 cu. ft. to which was added 65 cu. ft. for the filling of voids in the slope paving.

From the foregoing it will be seen that the two methods of testing the flow through the main checked very well, and give a good foundation for computing the flow through a small main at low velocity.

If, in "Kutter's formula," a coefficient n, be taken at .015, then the equation

$$V = c\sqrt{RS},\ \text{becomes}\ V = 73\sqrt{.292\times.000{,}455},$$

or,

$$V = 73\times.0115 = .8395\ \text{ft. per sec.}$$
$$\text{Discharge} = 1.069\times.8395. = .897\ \text{cu. ft. per sec.}$$

This is less than the weir discharge calculated, by 6%; and less than the rate found by filling the reservoir, by nearly 10%. It would show that the coefficient, n = .015, was very near the truth for this particular case. A part of the difference between this last result and the former ones is explained by the fact that in constructing the pipe an attempt was made to compensate for the rivet heads by making the smallest rings a slight fraction of an inch larger than 14 ins. In the lighter metal this difference is about ⅛-in., and in the heavier, about half of that. As a considerable portion of the pipe is under light head this allowance may mean an increase of several per cent. (3 to 5) over the calculated flow.

These experiments were not made in an ultra-refined manner, but were such as can be carried on at small expense and in ordinary practice. Neither was there time or money for making the test extremely accurate. It was only desired that the city know its supply with reasonable accuracy and as quickly as possible.

The tests show that it is unsafe to calculate on a coefficient of friction of less than .015, even for small mains at low velocity. Later experiments may determine (as outlined by Rudolph Hering, C. E., in Engineering News of Jan. 23, 1896,) that 0.16 is more nearly true. But for the present nothing less than .015 should be used for riveted steel mains having protruding rivet heads on the interior surface of the pipe.

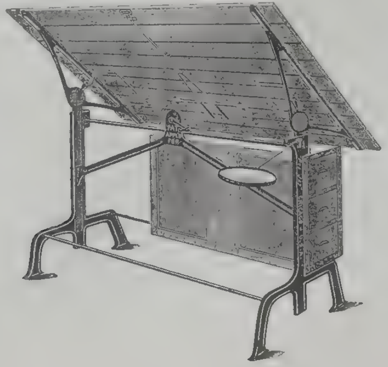
THE PEN-JAY ADJUSTABLE DRAWING TABLE.

We illustrate herewith an adjustable drawing table which has been put on the market recently by Post & Jacoby, of Chicago, and which is claimed to be especially easy to adjust and unusually firm and rigid in position for an adjustable table. The illustration shows an underneath view. To raise and lower the table it is only necessary to turn the small crank shown. By means of a continuous screw this crank revolves the horizontal shaft carrying pinions at its end which gear into and operate the rack attached to the uprights which carry the top of the table. The inclination of the table is adjusted by means of clamps operated by the handle shown just underneath the front edge. A pull on the handle loosens the clamps, which fly back into position as soon as the table is brought to the position desired and the handle released. The illustration shows clearly the cabinet, which is of polished hard wood. This table is put on the market in four sizes, ranging from 31 × 42 ins. to 48 × 72 ins., and these two sizes cost, respectively, $20 and $42. A number of these tables are used in the engineers' offices of the Sanitary District, of Chicago, and have proved very satisfactory.



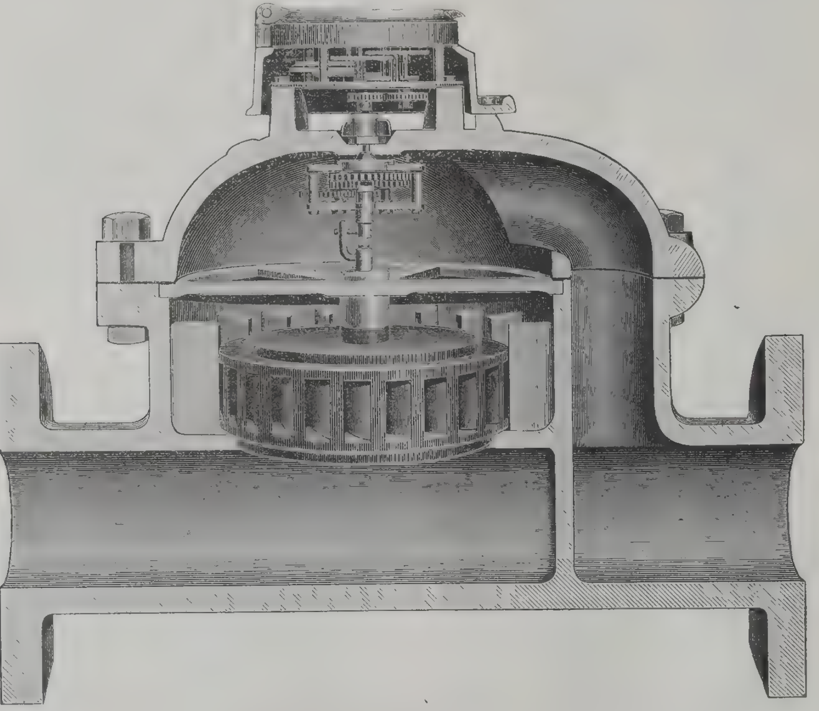
View of Underside of "Pen-Jay" Drawing Table, Showing Adjusting Mechanism.

Post & Jacoby, Chicago, Ill., Builders.

THE TORRENT WATER METER.

The increasing favor with which water meters are being received is stimulating manufacturers and inventors to attempt improvements to old forms, and to devise new ones. One of the latest candidates for favor among water-works officials is known as the Torrent meter, and is shown by the accompanying cut.

This meter is designed to record large volumes of flow with very slight loss of pressure. It is a current meter, with a horizontal wheel piston, running between directing and receiving vanes. The piston subdivides the current into small jets, which pass through it in horizontal lines, thus obviating vertical thrust on the bearings. The meter is made by the Hersey Manufacturing Co., of South Boston, Mass.



THE TORRENT WATER METER.

THE POETSCH FREEZING PROCESS FOR SHAFT-SINKING AT VICQ, BELGIUM.

In its "Abstracts of Papers" the Institution of Civil Engineers publishes an interesting account of a recent application of the Poetsch freezing process to the sinking of a shaft through nearly 300 ft. of water-bearing ground. The Anzin Mining Co. proposed to open a new mine at Vicq, in the valley of the Scheldt. The ground overlying the coal deposit was of a loose and water-bearing nature, and in sinking neighboring pits the outlay had amounted to $1,100 per yd. of depth, and a long time was required for completion.

A preliminary boring, made in 1892, gave the following section of materials to be penetrated:

	Ft.
Fine sand and alluvial gravel	22.14
Compact argillaceous sandstone	13.12
Chalk, loose and incoherent	65.44
Chalk, compact	138.74
Chalk, marl, with flints	59.04
Blue marls	82.00
Plastic clay	190.24
Green sand	44.75
Coal measures marked at	615.49

These measures were all water-bearing down to 298½ ft. below the surface, when a secure foundation for tubbing could be found in the blue marl under the flinty chalk. Flowing springs were found at two levels; one in the sandstone, of 2,700 gallons per hour, and one in the loose upper chalk; the latter being under pressure, rising 2½ ft. above the surface and flowing.

To provide the feed and condensed water for the freezing plant, an estimated demand of 3,500 gallons per hour, a well was sunk at a distance of 820 ft. from the site of the shaft. This well, though only 6½ ft. in diameter and 39 ft. deep, cost $2,000; the last 15 ft. being bored while the upper part was secured by an iron cylinder with a cutting edge.

Two pits of unequal size were to be sunk; one, 12 ft. in diameter, was intended for the pumping, ventilating and passenger hoists, and the other, 16.4 ft. in diameter, was to be fitted with eight tubs capable of raising 300,000 tons of coal per annum. The first thing done was to bore 36 holes for the reception of the circulating pipes; 20 of these were arranged around the larger pit in a circle 21.3 ft. in diameter, and 16 around the smaller pit in a circle 16.73 ft. in diameter. They were all of the same depth, or 298½ ft., and the two pits were 121 ft. apart. All springs encountered were trapped to prevent a circulation of water through the ground.

The freezing circuits, the most important element of the plant, were made of steel pipes, arranged in series; one, 1.17 in. in diameter and 0.156 in. thick, being placed concentrically inside another, 4½ ins. in diameter and 0.273 in. thick. Each series was connected by a goose-neck to its own ring-main, and the freezing fluid was passed down the inner pipe and returned through the outer one back to the refrigerator. Extreme care was taken in making and testing these tubes. The ring-mains were 7.8 in. in diameter; and the cold fluid moved at a speed of 4 ins. per second in the small tubes and 4.43 ft. per second in the larger pipes. The calculations by the engineer called for the abstraction of 110,000,000 calories from the ground about the larger pit, and 90,000,000 from about the smaller one; or, allowing 25% for losses, about 250,000,000 calories as the total heat to be removed. The time required to freeze the ground was estimated at 1,000 hours, or about 40 days.

The Linde freezing machinery was used. The calcium chloride solution in circulation measured 16,380 gallons and contained 25 tons of the dry salt, costing $30 per ton and the density of the solution was 1.25. The progress of the freezing operation was watched by sinking a series of thermometers 6½ ft. deep and about 3 ft. 3 ins. outside the ring of freezing tubes.

The freezing machine was started with one compressor on May 28, 1894, the ground temperature then being 11.65° C., and the cold developed being represented by 285,000 h. u. per hour. The next day the temperature had fallen to −47° C. in the refrigerator and to −1° in the return pipe; a second cylinder was then started, which reduced the temperature of the solution to −7°, and to −4° on the third day, when the third compressor was started. In 10 days more −10.6° was obtained in the cold solution, and then the whole four compressors were worked from June 12 to July 1, when the temperature was −15° C. in the supply pipes and the freezing of No. 2 pit was complete. Until July 17, only two compressors were now used, and on this date the initial freezing operation was considered finished and the ice-walls were maintained by working three compressors until Sept. 2 and two until Dec. 1, when the machine was stopped during the day and on Sundays and holidays. On Dec. 28 its use was discontinued, after working 7 months with 76½ hours stoppage in that time. The thermal equivalents of the work done in this period is shown in the following table:

	Calories.	
Heat absorbed in:	Pit No. 2.	Pit No. 1.
Formation of ice	43,040,000	70,075,200
Cooling ground, outside circuits	16,825,615	28,285,845
Cooling ground, inside circuits	14,473,982	22 917 860
Cooling work utilized	74,339,597	121,278,905
Surface losses	25,574,640	32,793,936
	99,914,237	154,072,841
Work done by engines:		
May 28 to July 2	100,379,694	....
May 28 to July 16	....	161,354,901

Sinking was commenced in the smaller pit on July 2, and in the larger on July 16, the grounds then being frozen in a ring 4 ft. thick, extending 18 ins. outward from the freezing center and 30 ins. inward in one case and 22 ins. and 40 ins. in the second case. By keeping the source of cold entirely outside the ground to be excavated, a large part of this ground was loose and the shovel could be used. Hard ground was wedged down, no explosives being employed. The chalk strata contained vertical fissures and here the maximum rate of sinking was 6½ to 8 ft. per day; but in the flinty strata below this the rate fell to 12 to 20 ins. per day. At this point the temperature in the pit was −12° C., the lowest reached. In this flint stratum the diameter of the unfrozen part was only 5.4 ft. in the large pit, and the small pit was entirely frozen. As showing the difficulties encountered, as many as 3,000 picks and wedges were blunted in one day in Pit No. 1. The blue marls at the foot of the shaft were entirely unfrozen, no ice being found at a greater depth than 34 ins. below the bottom of the freezing circuits in either pit. The actual time consumed in sinking the two pits through the 298 ft. of frozen ground was from July 2 to Oct. 5 for the small pit, and from July 16 to Oct. 16 for the larger pit, including 9 days of stoppage for building the first ring of tubbing. This tubbing was of cast-iron rings, built up of segments and backed on 8 ins. of concrete, the latter mixed with water containing 10% of calcium chloride to prevent freezing.

The total cost of sinking was about $142,000, or about $183 per ft. A summary of items is given as follows in meters and francs:

	Per cent. of total.	Total francs.	Per meter francs.
Patentee's royalty	4.6	32,760	139.20
Temporary plant and buildings	2.7	19,582	83.25
Boring for freezing tubes	10.4	73,673	313.10
Freezing plant	35.0	248,765	1,057.20
Measuring apparatus	0.3	1,898	8.10
Freezing	4.7	33,030	140.40
Sinking and tubbing	40.5	287,454	1,221.65
Carriage	0.6	4,562	19.40
Tools	0.7	5,257	22.35
Sundries	0.4	2,865	12.15
Totals	100.0	709,850	3,016.80

In this statement the whole cost of the plant is charged to this single use; its subsequent employment in future sinking would be worth 1,000 francs per meter, leaving the work done here to cost about 2,000 francs per meter. The items especially chargeable to the freezing operations amounted to about 660 francs per meter, or, say, $40.24 per ft. About 20% of the cooling effect was lost at the surface owing to the distance of the machines from the work; the engines used being intended to eventually drive air-compressors in working the mine. The authors of the paper, MM. Saclier and Waymel, also think that each pit should have had its separate freezing plant, so as to be enabled to get to work as soon as an ice-wall of sufficient thickness had formed over the surface. They could then have excavated in softer ground and advanced more rapidly. Especial stress is laid upon the necessity for absolutely vertical borings for the freezing pipes; and the maximum distance between holes should not be more than 4 ft. to depths of 328 ft., and for greater depths it would be well not to exceed 3.28 ft. The original of this paper is to be published later in full, with 14 plates, by the Institution of Civil Engineers.

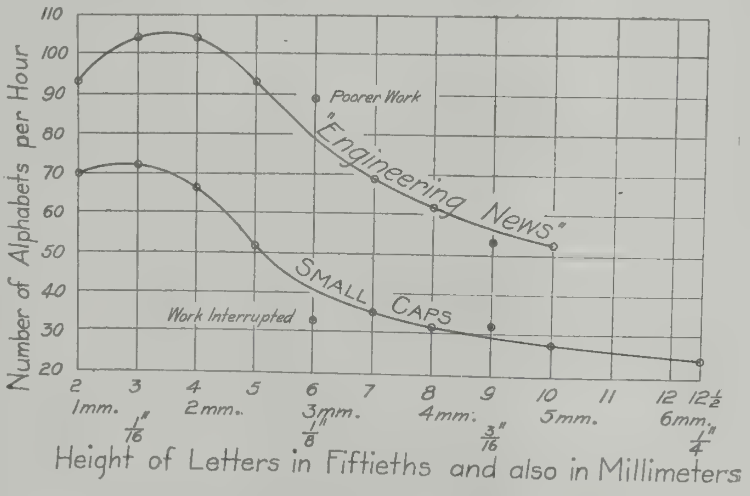
RELATIVE ECONOMY OF DIFFERENT HEIGHTS AND STYLES OF FREE-HAND LETTERS.*

By R. C. Vial.**

It is well known by any one who has done free-hand lettering that different heights and styles of letters require different lengths of time for execution. The writer, not having seen any data on this subject, made a series of experiments to determine the relative time required to form letters of different styles and sizes. These experiments comprised the formation of 1,200 alphabets or over 31,000 free-hand letters. The experiments were undertaken for the writer's personal benefit and satisfaction, and were not originally intended for publication.

The object of the work was to determine the relative economy of letters of different heights and styles. Two styles of letters were used viz.:—inclined small capitals (single stroke Gothic letters) and inclined lower-case letters of "Engineering News" style. In the execution of the work it was desired simply to do fair work combining quantity and quality. In each experiment greater quantity could have been obtained by sacrificing quality, or better quality of less quantity might have been shown. The rate of work was somewhat faster than ordinary office work of similar character. Nothing was permitted to interrupt the work during an experiment. In each case the length of an experiment was one hour, i. e., 60 consecutive minutes, the pen not being laid down between the time of the beginning and the end of each experiment. For uniformity throughout the tests, the letters of each experiment were made in alphabetical order. Guide lines for top and bottom of letters were penciled previous to the beginning of an experiment, but none of the letters were penciled. With each alphabet the work began with letters 2-50-in. high, the height being increased 1-15-in. for each succeeding experiment. A Keuffel and Esser lettering pen was used on the smallest letters. The remainder of the work was done with a Spencerian No. 1. The quality of work was kept as nearly uniform as possible.

In the accompanying cut the results of the tests are graphically shown. The heights of letters, in fiftieths of an inch with equivalents in sixteenths and in millimeters, are platted as abscissas, and the number of alphabets formed per hour as ordinates. The curves passing through the points thus located show that of the two alphabets used the "Engineering News" style is much the faster; and that in each case the most economical letter for the writer is one about 3-50-in. high. The difference in speed for the two styles is accounted for by the different number of strokes in each alphabet. In an alphabet of the small capital letters there are about 60 strokes, and in the "Engineering News" alphabet less than 35. In other words it takes about half as many strokes of the pen to form an alphabet of "Engineering News" style as it does to form one of small capitals. In forming a letter the most care is required at the beginning and at the end of each stroke.



RELATIVE SPEED OF FORMING DIFFERENT ALPHABETS.

Probably no other person would, in a similar set of experiments, get the same results as those here given, nor is it certain that the writer himself could produce exactly the same data a second time. The actual results given apply to him only, but it is believed that the comparative results are farther reaching. It is with the latter point in mind that this paper has been presented.

WORK ON THE MELAN BRIDGE at Topeka, Kan., is to go forward at once. Legal difficulties in connection with the issuance of bonds for the work have delayed matters several months; but these are now at an end. The bridge was illustrated and described in our issue of April 2.

ASPHALT FROM CLINE, UVALDE COUNTY, TEX., is to be laid on eleven blocks of First St., at Troy, N. Y. The bids were opened July 14 and were published in our Construction News Supplement of last week under Contract Prices.

COAL HAS BEEN FOUND at Vicksburg, Mich., in boring a test well for the new water supply system for which Messrs. Alvord & Shields are the engineers. The coal was found at a depth of about 50 ft., the vein being 3 to 4 ft. in thickness.

THE CABLE UP THE AMAZON RIVER, from Para to Manaos, which was laid last winter by the cable-laying steamer "Faraday," was only in operation 32 days when it parted. Five different breaks have been found and the cable is not yet in operation. At some points the current is said to reach 8 to 10 miles per hour, and this, with the sunken drift, etc., makes the life of the cable uncertain.

AN 1,800-HP. VERTICAL ENGINE has recently been built for the Whitman Mills, New Bedford, Mass., by the Rice & Sargent Engine Co., of Providence, R. I. The use of vertical engines of large size is very common abroad, especially in textile mills; but comparatively few have been built in this country. The engine is a compound, with cylinders 28 and 60 by 48 ins., and the speed is 100 revolutions, making a piston speed of 800 ft. per minute, with steam of 160 lbs. pressure. The engine drives a flywheel 16 ft. in diameter, grooved for 44 1¾-in. ropes. All the valves of the engine are in the cylinder heads. The clearance space is only 3% in the h. p. cylinder and 2% in the l. p. cylinder. A reheating receiver is bolted to the rear of the column supporting the h. p. cylinder. The governor regulates the cut-off of both cylinders and the cut-off of the l. p. cylinder is also adjustable by hand.

A SYSTEM OF ELECTRIC LIGHTING is to be established in the City of Mexico. Bids are asked for a plant furnishing 150 incandescent and 600 arc lights. Of the arc lights 480 are to be of 2,000 c. p. and 120 of 1,200 c. p. At the expiration of eight years the city is to have the option of buying the entire plant.

A NEW METHOD OF WOOD PRESERVATION is described as follows: The heavy oils and waxes which are left after the distillation of petroleum or other oils are dissolved in naphtha, and the solution is forced into the seasoned timber in the same manner as in creosoting. The timber is then heated and the naphtha evaporates and is recovered in a cooling chamber, the process being in fact similar to distillation. The heavy oils and waxes are left in the cells of the wood and make it thoroughly water-proof, but clean to work and handle, light and elastic. We take the above from a stray newspaper clipping, the origin of which we do not know; but the scheme seems to be a meritorious one. It may be pointed out, however, that the very great risk of fire and explosion in handling naphtha would make the process hardly applicable on a large scale to compete with creosoting, burnettizing and similar processes, and it would probably be better adapted to the treatment of woods for cabinet-making and similar uses.

BOOK REVIEWS.

ALDEN'S LIVING TOPICS CYCLOPEDIA.—A Record of Recent Events and of the World's Progress in All Departments of Knowledge. Abbas to Coudert. New York: John B. Alden; 12mo.; half leatherette; pp. not numbered; $1.

The first few pages of this publication were noticed in our issue of April 2, 1896, so no further comment is necessary.

SPECIFICATIONS.—A Practical System for Writing Specifications for Buildings. By W. Frank Bower. New York: Edw. A. McLean, 14 Lafayette Place; 4to.; cloth; pp. 229; $5.

The preface to this book states that it is not intended to be a treatise on specifications, but simply an arrangement of the matter commonly used in writing specifications in such a form that the latter may be easily and quickly performed without omitting essentials. The specifications proper are printed on the left-hand page in large type, with ample room for interlineations. Italics are used to indicate items likely to vary with different jobs. On the right-hand page are notes thought to be of value in writing specifications, or where none are deemed essential the page is left blank.

VITRIFIED PAVING BRICK.—A Review of Present Practice in the Manufacture, Testing and Uses of Vitrified Paving Brick. By H. A. Wheeler, E. M., Clay Specialist of the Missouri Geological Survey. Indianapolis: T. A. Randall & Co. 8vo.; pp. 84. $1.

This is a most excellent little book along the lines indicated in the sub-title, and especially meritorious for its discussion of the various clays employed. The information here given on clays and their manipulation, including the whole process of manufacturing vitrified paving brick, is really needed by any one who has to make use of this material in engineering work and especially for street paving. The various methods of testing paving brick are discussed concisely and intelligently. The book would be a good one for street superintendents and for commissioners of streets and public works who have to do with the selection of paving materials, as well as for engineers.

STATISTICS OF THE AMERICAN AND FOREIGN IRON TRADES FOR 1895.—Annual Statistical Report of the American Iron and Steel Association, containing Complete Statistics of the American Iron Trade for 1895; also a Brief Review of its Present Condition; also a General Review of the Iron and Steel Industries of the United States from Colonial Times to the End of 1895. Published by the American Iron and Steel Association; General Manager, James M. Swank, Philadelphia, Pa. Paper; 8vo.; pp. 78. $3.

This statistical report was issued in May, and is brought very closely down to date, including many figures and prices of the first quarter of 1896. We have, as usual, published an abstract of the report (Eng. News, June 11), showing the general condition of the iron and steel and allied industries, as brought out by the many detailed statistical tables. There are seven pages of a necrology, which is defective in that all the notices of deaths are arranged in two unbroken paragraphs (one for 1895 and one for 1896); it would have been much better and more convenient to have given a separate paragraph to each notice, which would occupy but little more space. At the end of the report is a review of the American trade, written by Mr. Swank, General Manager of the Association, which commences with the attempts in iron-making made at Falling Creek, Va., in 1622, and at Lynn, Mass., in 1645. This review occupies 12 pages.

JOHNSTON'S ELECTRICAL AND STREET RAILWAY DIRECTORY FOR 1896.—Containing Lists of Electric Light Central Stations, Isolated Plants, Mining Plants, Street Railways (Electric, Horse and Cable); Telegraph Companies, District Messenger Companies, Telephone Companies; Manufacturers of and Dealers in Electrical and Street Railway Apparatus, Machinery and Supplies. New York: The W. J. Johnston Co., 253 Broadway. 8vo.; cloth; pp. 828. $5.

Aside from being a directory of the industries named, this volume gives the paid-in capital stock of the electric light and street railway companies and a slight amount of information regarding the character and extent of the several plants. For central lighting plants the system in use, the number of arc and incandescent lamps and the horse power of the plant is stated; in addition an asterisk indicates that the company has a contract for city lighting and a dagger that it furnishes current for power purposes. For street railways the mileage, number of cars and system in use is given.

We do not find in the book any figures for the number of industries included, of the several kinds named, but we learn from the publisher that there are listed 2,711 central electric light stations, located in the United States, Canada, Mexico and Cuba; 1,140 street railways, of which 828, with a mileage of 14,850, are operated by electric, and 312, with a mileage of 2,300, by horse, steam or cable power; and 7,150 manufacturers, dealers, electrical engineers, etc., the latter being arranged, first geographically, second, according to business, and third, alphabetically.

One of the most valuable features of the work, to some, is the information regarding the rates charged for public lighting in 350 cities. It seems surprising that this list should be so short.

SEWERAGE AND SEWAGE PURIFICATION.—By M. N. Baker, Ph. B., Associate Editor, Engineering News, Joint Author "Sewage Disposal in the United States." Author "Sewage Purification in America." New York: D. Van Nostrand Co. 16mo.; boards; pp. 144; 50 cts.

This little book is written to replace No. 18 of the well-known Science Series, the original volume, by Professor Corfield, having appeared in 1875, and being entirely unadapted to existing American conditions. The present volume has been prepared absolutely without reference to the old one, further than to cover the ground indicated by the title, and perhaps a little more.

The book is popular, rather than technical, and is not designed for engineers well up in sewerage and sewage purification. Engineers who have followed other lines of practice may find this little volume a convenient means of ascertaining the general outlines and principles of the subject in the light of modern theory and practice. Sewer commissioners and public officials whose duties make desirable some knowledge of the subject, may make this volume, with its references to more elaborate treatises, a basis for more extended reading, if they find it does not contain all they need or awakens such interest in the subject as to create a desire for more information.

While originality in the subject matter is, in such a well-worked field, out of the question, the method of presentation in some respects differs from previous attempts, so that even the sewerage engineer of long experience may perhaps find here new ways of presenting old facts when called upon to impress municipal authorities with the necessity of providing a good system for both the collection and final disposal of sewage.

The above remarks, with the title of the volume, will be sufficient to indicate the character of its contents.

ARTESIAN WELLS AS A MEANS OF WATER SUPPLY. —Including an Account of the Rise, Progress and Present State of the Art of Boring for Water in Europe, Asia and America; Progress in the Australian Colonies; a Treatise on Water Bearing Rocks; Permanence of Supplies; the Most Approved Machinery for and the Cost of Boring, with form of Contract, etc.; Treatise on Irrigation from Artesian Wells; and on Sub-Artesian or Shallow Boring, etc. By Walter Gibbons Cox, Assoc. Inst. C. E. Brisbane: Sapsford & Co.; 8vo.; cloth; pp. 146; illustrations; 7s. 6d. For sale by D. Van Nostrand Co., New York; $3.

Considering its pretentious title page and its American price this volume contains but a small amount of information of use to engineers, and for much of that the author is to be credited simply with having brought it together, mostly from the Government reports of various countries. Yet the entire absence of a modern book on the subject, and of any book in English,* so far as we know, may render this one of considerable interest and some practical value to engineers who do not have access to the government publications treating this subject.

In our issues of Feb. 14 and 21, March 14 and 28, and April 4, 1891, we published abstracts of a U. S. government report on the artesian wells of the West. Our abstracts related more especially to geological conditions, and the development and practice in West, but the report reviewed artesian well experience elsewhere, and contained, probably, nearly everything of value to Americans in the volume being noticed, besides much in addition. These reports of our government, however, cannot now be obtained easily, if at all, we believe, and have the great disadvantage of being very prolix and poorly edited, largely owing to the haste with which the investigation was made.

FINAL DISPOSITION OF THE WASTES OF NEW YORK.—Report by Department of Street Cleaning, George E. Waring, Jr., Commissioner. 8vo.; paper; pp. 159; tables and 13 illustrations. Address the Commissioner.

This is without question the most valuable report on the disposal of garbage, ashes and the multitudinous other forms of city refuse not coming under the comprehensive term sewage which has ever been published in this country and we know of nothing equal to it yet published abroad. Most reports on investigations of this kind are limited to a general discussion of the subject and more or less superficial descriptions of garbage disposal plants seen on a hurried trip through the country. "Junketing trip" is the name commonly applied to such journeys, especially by the newspapers in opposition to the city government of the time.

The main part of the report is dated Feb. 28, 1896. In our issue of Feb. 20, 1896, we abstracted from advance pages some of the information given in the report. There has since been added a number of illustrations, mostly views of garbage utilization plants, and an appendix giving the various steps which led up to the recent award of a contract for the disposal of garbage alone, by the Arnold utilization process (see Eng. News, March 28, 1895), the contractor being the New York Sanitary Utilization Co. Some other valuable matter has also been added, and some revised and extended.

As the report now stands it describes a number of garbage utilization processes and gives some figures of results obtained from the treatment of large quantities of garbage. It discusses the grease, fertilizer, old bottle, paper and junk trade in general, and presents estimates of the quantities of some of these materials to be derived from the wastes of New York and their market value. An interesting section treats of the uses to which clean ashes can be put in this vicinity. Besides this there is some general discussion of the subject in hand, with sensible remarks on its possibilities and limitations.

AMERICAN STREET RAILWAY INVESTMENTS.—Published Annually as a Supplement to the "Street Railway Journal." Third Edition. New York: Street Railway Publishing Co.; cloth; 4to.; pp. 333; 47 maps; $3.

The general structure of this edition is practically the same as that of last year, the principal change being in the presentation of balance sheets and the arrangement of operating statistics for four years instead of for three. The publishers call special attention to the fact that out of 1,112 operating and leased street railway corporations whose financial reports are given, only 8½% have not been heard from officially. Of the 1,444 reports, including new corporations, presented, 988 have been corrected up to some month in 1896 (chiefly April and May), 305 have been corrected up to some month in the last half of 1895, while only 151 bear a "date of information" prior to June 30, 1895. This is said to be the only financial manual in the steam or street railway field in which all information is dated, so that old reports may be distinguished from new and the present authentically determined. In general, the following information is given in regard to street railway companies: A brief history of the company; a statement of the capital stock authorized and issued; a description of the funded debt direct, assumed and guaranteed; a statement of any peculiarities of the mortgage bond issues, sinking fund requirements, purpose for which treasury bonds may be issued, etc.; of leased properties with terms and conditions under which they are operated; of the franchise terms and obligations; a general operating report for the last four financial years with later earnings wherever possible; detailed operating expenses for the last four financial years; statistics of traffic for the same period; balance sheets for the last two or more years; description of the plant and equipment; officers, directors, and location of general office; also reference to descriptions of the company's property, or of other matter of general interest found in the files of the "Street Railway Journal" for the last five years. This edition contains 47 maps, some of which are especially large and interesting.

PRESS-WORKING OF METALS.—A Treatise upon the Principles and Practice of Shaping Metals in Dies by the Action of Presses, together with a Description of the Construction of Such Implements in Their Various Forms, and of the Materials Worked in Them. By Oberlin Smith. Illustrated with 433 engravings. New York: John Wiley & Sons; 8vo.; pp. 275; $3.

Mr. Oberlin Smith is well known to the mechanical engineers of this country as the president of the Ferracute Machine Co., of Bridgeton, N. J., whose specialty is the manufacture of presses, punches and dies. With a personal experience of many years in this line of work, and with exceptional ability as a writer, he is well qualified to produce just such a work as the one before us, on a subject of which the existing literature is extremely scant. There is scarcely a machine shop or a manufactory in which metals are used which does not have one or more punching, drawing or embossing presses and some one person at least who is interested in the theory and practice of the art of shaping metals by means of these implements. To such this work will be very welcome. It is written in a style which everyone can understand; it contains a great variety of useful information, and the typography and engravings are excellent. Mr. Smith is an expert on the subject of wire gages—he has invented one himself—and he has collected and published in this book a table containing no less than 25 different gages, devoting a whole chapter to their discussion. The following extract, which is a good example of the author's style, gives his opinion of the latest American "Standard" gage.

> It was Carlyle, if I remember right, who said that the population of England was so many millions—mostly fools. However indignantly we may repudiate the descriptive portion of the distinguished cynic's remarks as applied to the people of our mother country in general, we can scarcely but admit the partial foolishness of that portion of the population that has been engaged at various times during a century past in the industry of inventing wire gages. In America, too, we find that either heredity, or example, or both, has caused a further development of this pernicious industry, and that the crowning absurdity of all its products has been legalized in the United States by an act of Congress taking effect July 1, 1893. One of the chief points about this remarkable latest "Standard" is that it is almost everything it should not be, utterly ignoring many attributes that should be embodied in a good gage.

PUMPS AND PUMP MOTORS.—A Manual for the Use of Hydraulic Engineers. By Philip R. Bjorling, Hydraulic Engineer. In two volumes; 4to.; Vol I., Text, pp. 369; Vol II., Plates; 261 plates, with 1,006 illustrations. London, E. & F. N. Spon; New York, Spon & Chamberlain. $18.

The most notable thing about these two volumes is that the two together measure 12¾ × 10½ × 3 ins., weigh 11½ lbs., and cost $18. The author has previously written four other books on pumps, viz.: Practical Handbook on Pump Construction; Practical Handbook on Direct-Acting Pumping Engines and Steam Pump Construction; Pumps, Historically, Theoretically and Practically Considered; The Construction of Pump Details. We cannot but admire the vast amount of labor that has been expended upon the drawings for this work; each one of the 1,006 illustrations is a photolithograph of a line drawing, made apparently especially for this work. The drawings, however, seem to have been made by a mechanical draughtsman without any knowledge of the artistic details necessary to make the work have a good appearance when reproduced and printed in a book. The section lining and the lettering are especially bad. The illustrations are printed only on one side of the paper; they are on the average about double the scale, or four times as large in area as there is any need for, thus making the volume of plates eight times as bulky as it need be. If these illustrations had been reduced to half their present lineal dimensions they would have had a much better appearance, and could then have been printed with the text describing them in the first volume, in which there is enough blank paper at the end of most of the 45 chapters, and in the extremely wide margins, to have made room for them all. The user of the book would then not have been obliged to handle two books to understand the text of one, and the cost of the work might have been greatly reduced. As an example of how not to build a book, this work is about the best that has come under our observation of late. It might be expected that an author who has already had the experience of writing four other books on pumps would by this time know how to write a good one, but in this expectation we are disappointed, for his method of writing is about as faulty as his method of book-making. His style is labored and verbose, and in many cases the meaning is difficult to comprehend. Of the 369 pages in Vol. I., about 50 pages are taken up with tables which are found in most engineers' reference books, so that the total amount of text is but little over 300 pages. To students of pump design the 1,006 illustrations may be valuable as a collection of pump drawings, and the text may be useful to explain the drawings.

HOW TO DRAIN A HOUSE.—Practical Information for Householders. By Geo. E. Waring, Jr., M. Inst. C. E., Consulting Engineer for Sanitary Drainage. Second Edition, with Annotations. New York: D. Van Nostrand Co. 12mo.; cloth; pp. 223; 33 illustrations; $1.25.

Although the main part of this book relates to conditions existing when it was originally written, in 1884, it still contains much valuable information for those who are about to build a house or who, having built, desire to satisfy themselves that proper sanitary precautions are in force. Notes are presented at the end of some of the chapters designed to record the progress made in the past ten years.

While the book is intended primarily for householders, engineers who have not had occasion to pay attention to plumbing questions will find many valuable hints here: doubly valuable, oftentimes, for the happy way in which they are expressed, making them available to bring home with force a lesson to some client or some city official or board which has asked for advice in drawing a plumbing code or health ordinance.

Some engineers will doubtless be both surprised and amused to see the following, given as a foot note in connection with the use of strips of muslin wound around drain tile joints when laid:

> This use of muslin is patented, but it is hereby dedicated to the public to the extent of its use under or within the foundation-wall of buildings.

As this note was written, presumably, in 1884, possibly the patent may have expired before this. In this connection a short chapter on the author's practice in patenting devices of his own invention and alluding to them in his book may be mentioned. One paragraph from this chapter is as follows:

> My own devices were in no case invented with a view to securing a valuable patent, nor for any other purpose than to improve my own professional practice. The few of these devices which have approved themselves to my later judgment, and which I am now introducing in my work, I have patented to secure an incidental commercial advantage. I shall therefore describe them without hesitation and without further comment, treating them exactly as I treat such of the inventions of others as I believe to be good. I shall trust to the good sense of the reader not to misunderstand my motive.

Whatever may be said for or against the taking out of patents by engineers, the frankness of the author in this chapter is certainly commendable.

A subject of much contention among engineers and plumbers is the desirability of placing a trap on the main house sewer, or the connection between the interior plumbing and the street sewer. The majority of engineers and sanitarians still favor the use of such a trap, so far as we can judge, but there are a number of eminent men who hold that it is far better to omit the trap, leaving an uninterrupted opening between the street sewer and the upper end of the soil pipe, where it extends through the roof. Col. Waring believes in the latter plan, as a general rule. There is much to be said for it, although the arguments are by no means all on one side.

The largest chapter in the book is the concluding one, on sewage disposal for isolated buildings, by sub-surface and surface irrigation.

AN OPPORTUNITY FOR AMERICAN ENGINEERS and investors is offered by the Government of New South Wales, which advertises for proposals for the manufacture and supply of 150,000 tons of steel rails, and the track fastenings to be used with them. All the material must be manufactured in New South Wales, and the delivery is to extend over a period of ten years. The proposals will be opened on Dec. 30, 1896. It is to be hoped that some American tenders may be submitted in this competition. Further particulars are given in another column and the specifications by which bidders will be governed can be seen at this office.

◆

PRICES OF M. C. B. COUPLERS are asked for by the Secretary of the Master Car Builders' Association, Mr. John W. Cloud, who is sending the following circular letter to M. C. B. coupler makers:

> Section 13, of Rule 5, of the revised code of Rules of Interchange, which goes into effect on Sept. 1, 1896, provides that "M. C. B. couplers, or parts of same, shall be charged at manufacturer's current market prices, or replacement prices, which are to be quoted by the Secretary Sept. 1, and March 1, of each year. When the coupler manufacturers do not quote a replacement price, and do not require the return of the scrap for the price quoted, the credits for scrap shall be allowed at the rates given in the above list."
>
> Under these revised rules of interchange, all car owners are chargeable with the repairs to their cars when away from home necessitated by ordinary wear and tear from fair service. Will you kindly quote, sometime prior to Aug. 20, the figures which I should publish to the members, as the current market prices, or replacement prices, for your coupler and parts thereof. John W. Cloud, Secy., M. C. B. Association, Rookery Building, Chicago, Aug. 3, 1896.

◆

PLANS FOR TRACK ELEVATION on the Erie R. R. in Jersey City are reported completed and ready for the approval of the city authorities. The present station will not be changed, but the tracks will rise from the station and cross Henderson St. at an elevation of 13 ft. above their present level. From this point the tracks will run on a steel viaduct to Monmouth St., where the descent to the tunnel will begin. The estimated cost of the work is $1,000,000.

◆

A GRADE CROSSING BATTLE took place at Bradford, Pa., on July 28, between the Western New York & Pennsylvania R. R. and the Bradford Electric Street Ry. Co., the former company trying to prevent the latter from laying a crossing over its tracks. In view of the constant dangers attending such grade crossings, managers of steam railway companies cannot be blamed for opposing them by every means in their power; but the only really effectual fighting is that done in the courts. The battle with employees at the crossing invariably does harm and seldom or never amounts to anything in preventing for any length of time the making of the crossing.

◆

THE BOYNTON BICYCLE RAILWAY at East Patchogue, Long Island, was sold by a court officer on July 30 to satisfy a judgment against the owners. The road is 1½ miles in length and was built to exhibit the bicycle railroad system. It was bid in for $3,310 by W. H. Boynton.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week, and the most serious that has occurred in the United States for eight years, or since the rear collision at Mud Run, on the Lehigh Valley R. R. in 1888, was a collision at a grade crossing of the Philadelphia & Atlantic City and West Jersey railways, near Atlantic City, N. J., at 6.50 p. m., July 30. The disaster was due to the engineman of a fast express train failing to apply the brakes soon enough to stop his train before reaching the crossing. The list of casualties is 46 killed and about 60 injured, according to the best information attainable. The circumstances of the accident are described at length in our editorial columns.

◆

A RAILWAY WRECK was caused on the Illinois Central Ry., Aug. 1, near Clinton, Ill., by failure to obey orders. Two passenger trains collided head on. Two persons were killed and seven injured. On Aug. 4, near Shamokin, Pa., a fast freight on the Philadelphia & Reading R. R. was derailed by a freight car door which had dropped on the track. A car loaded with powder exploded and set fire to the train. Two persons were killed and one injured.

◆

A RAILWAY BRIDGE FAILED on the Vandalia Ry. near Crawfordsville, Ind., July 29. Fearing that the bridge was unsafe a locomotive was run across ahead of a passenger train to test the bridge. The locomotive was running at about 30 miles an hour and when near the center of the bridge it collapsed. Three of the five men who were on the engine were killed.

◆

A HEAVY STORM occurred throughout Ohio and Indiana on July 29. At many places buildings were blown down or washed away by high water. A number of people are reported as killed and injured at various places.

◆

THE EXPLOSION OF A POWDER MAGAZINE occurred at Funfkirchen, Hungary, on July 30. Five persons were killed and about 100 injured.

◆

AN EMPTY STILL EXPLODED in an oil refinery at Jersey City, July 31, seriously injuring five men. A workman was inspecting the interior of the still while another held an incandescent lamp through the manhole. The lamp swung against a piece of iron, the glass was broken, and the glowing carbon ignited the mixture of gas and air in the still.

◆

THE STRIKE AT CLEVELAND by the employees of the Brown Hoisting & Conveying Machine Co. has been resumed. On July 31 the company issued a letter to the press stating that the strike had been settled on the terms offered by the company the day after the commencement of the strike. These terms had been agreed to by the attorney for the strikers, who were ordered back to work. When the men applied for reinstatement the Brown company asked each individual if he understood the terms of the agreement, which stated in particular that all contracts by the company would be with individuals and not with the union. This brought on the strike anew and there is said to be danger that all union men in the city will quit work.

◆

THE SEPARATION OF ASHES, GARBAGE and rubbish and the placing of it in three separate receptacles, was inaugurated in New York city, Aug. 1. The garbage will be treated by the Arnold utilization process, under the contract recently awarded. It is expected that the ashes will be used for filling purposes. Bids are now invited for the privilege of sorting the rubbish.

◆

A 66-IN. RIVETED STEEL WATER MAIN, about 15 miles long, will be laid for the city of Brooklyn, as an extension to its present water supply system on Long Island. Bids for this extension were received on June 11, and were published in our Construction News Supplement for June 18. The successful contractor is Mr. John McNamee, of Brooklyn. From the reports at hand it appears that asphalt will be used to coat the pipe.

◆

THE PASSAIC VALLEY SEWAGE COMMISSION, appointed a few weeks ago to report on a plan for preventing the pollution of the Passaic River, has held a number of meetings in the various municipalities interested and taken a trip to New England to visit sewage disposal plants. A few days ago it appointed Mr. A. Fteley, M. Am. Soc. C. E., as Consulting Engineer, and Mr. Chas. E. A. Jacobsen, formerly engineer of the Newark water department, as engineer to the commission.

◆

PLANS TO PREVENT THE FURTHER POLLUTION of the Elizabeth River at Elizabeth, N. J., have been prepared by Mr. Francis Collingwood, late Secretary Am. Soc. C. E. The plan is said to include an intercepting sewer some three miles long, 2½ × 3¾ ft. at its upper and 5½ ft. in diameter at its lower end, with a pumping station about one-half mile from the lower terminus.

BIDS FOR A NEW WATER SUPPLY for Jersey City will be received on Aug. 24. Bids are invited for a gravity supply on three different plans and for a filtered supply from the Passaic River, the present source. The plans for a gravity supply call for water delivered at 127 ft. and at 210 ft. above mean high tide, and for at least one-third of the supply delivered at 210, and the balance at 127 ft. The system must have a daily capacity of 35,000,000 gallons, and be increased, on order, to 50,000,000 gallons. The city will have the option to buy the works at intervals during the contract. The filtered supply must be of 35,000,000 gallons capacity and must be lifted to existing reservoirs with triple expansion, high-duty, condensing engines capable of working against 140 lbs. pressure. A boiler plant must be provided and a conduit to the city reservoirs. The character of the filter plant is not restricted further than that it must yield the requisite amount of water with no more than a trace of nitrites, and that the water must be transparent and free from color, odor, turbidity, alkaline or acid tastes. The contractor must agree, further, that the filtered water shall conform to a standard of purity laid down by him, which must state its contents, organic matter, free and albuminoid ammonia, nitrates and bacteria.

◆

THE PROPOSED INTERNATIONAL DAM across the Rio Grande at El Paso, Tex., is still under discussion. In the July number of the "Irrigation Age," a journal published at Chicago, a brief article reviews the history of the scheme, and sets forth its present status. In 1888, 1889 and 1894, the article states, the river was dry for a considerable period, while since June 1 of this year there has been no flow. The seasons named, or some of them, are said to have been exceptionally dry, and no statement is made regarding the usual dry weather flow of the stream. It is said that the Mexican government has formulated a claim against the United States for $22,000,000 damages on account of the loss of crops during the past ten years through diversion of the waters of the stream above the boundary line. It is also stated that Mexico will waive these claims if the United States will dam the river and give Mexico half the surplus water stored. A dam site has been proposed about two miles above El Paso, where it is said a structure 60 ft. high and 500 ft. long would form a reservoir 15 miles long with a storage capacity of 4,000,000,000 cu. ft., sufficient to irrigate 100,000 acres on each side of the river, also giving a large amount of power. Since this plan was formed it is said that a scheme has been put under way to irrigate from another reservoir the very lands that would be submerged by the international dam.

◆

THE PROPOSED WATER POWER FRANCHISE at Sault. Ste. Marie, Mich., noted in our issue of July 30, has been passed unanimously by the city council. Work must be started within six months. It is said that a large amount of power will be developed, and that Mr. E. V. Douglass, of Philadelphia, is president, and Mr. F. H. Clergue, of New York, is vice-president, of the Lake Superior Power Co., which will carry out the provisions of the franchise.

◆

THE PLANS FOR RAISING THE STEAMSHIP "AILSA are almost completed. It is proposed to raise the vessel by means of large barrel shaped wooden cylinders, 30 ft. long and 8 ft. in diameter. The cylinders will be filled with water and submerged so that they can be fastened by chains beneath the hull. Compressed air will then be forced into the cylinders. Twenty-four cylinders will be employed. The "Ailsa" was sunk on Feb. 29, 1896, by the French steamer "La Bourgogne," in the channel leading out of New York Bay. The "Ailsa" is lying in comparatively shallow water.

◆

A TEST OF THE ADHESION OF CONCRETE TO IRON has recently been made in connection with a piece of concrete and iron construction now going on in Milwaukee, Wis. A block of concrete, 16 × 3 × 4 ins., with a 1-in. square bar of twisted iron passing lengthwise of it was heated to a red heat for about 20 mins. in a furnace, and was then plunged into a bath of cold water until it was cooled throughout. Upon removal the concrete was found to be somewhat soft and friable, but it soon became hard again. There were no signs whatever of any separation of the iron from the concrete nor was the concrete cracked along the line of the iron bar or anywhere else. The least depth of the iron from the surface of the concrete was about 1 in. It will be noticed that the construction was the well-known concrete and twisted iron construction of the Ransome & Smith Co., of Chicago, Ill.

◆

AN AERONAUTICAL CONVENTION is to be held in Boston, Mass., in September, under the auspices of the Boston Aeronautical Society. A prize of $150 will be given for the best designed kite, and a special prize of $100 is offered by Mr. Octave Cleomite, Past-Pres. Am. Soc. C. E., for the best monograph on the kite.

◆

THE HOLMAN FRICTION-GEARED LOCOMOTIVE is said to have attained a speed of 94.7 miles per hour on the South Jersey R. R., near Cape May, N. J., on July 29.

THE NEW STEEL ARCH OVER THE NIAGARA GORGE.

By Orrin E. Dunlap.

(With inset.)

One of the greatest bridges to be erected this year is the new steel arch to span the Niagara chasm on the site of the present railway suspension bridge now leased by the Grand Trunk Railway of Canada. The fact that a steel arch is to succeed this grand structure is remarkable in itself, for this suspension bridge was the first work of the kind in America, and was built to facilitate travel between the East and the growing West. It is a structure which, despite all the changes it has undergone in construction, has ever since the day of its completion afforded a constant service to trains, carriages and pedestrians.

It was on April 23, 1846, that the company received its American charter, and on June 9, 1846, a charter was obtained in Canada. In commencing work on the bridge the first difficulty that presented itself was to secure a means of communication from cliff to cliff, and this obstacle was overcome by a boy named Homan Walsh, who one afternoon while flying his kite allowed it to settle on the Canadian bank. This little kite string served to pull a cord across the river, which in turn was followed by a rope and later by a wire cable. On the wire cable so erected a car was operated both as a ferry and to facilitate the great work of building the bridge. This cableway, probably the first in America, was used for the first time on March 13, 1848. The basket used was designed by Judge T. G. Hulett, who is still living in Niagara Falls. This basket was made of strips of band iron varying in width from an inch to an inch and a half, fastened with rivets. As seen in Fig. 3, it is higher at the ends than in the center. There is a seat at each end, their depth being about 2 ft. The manner in which its shape was decided upon is most interesting. In December, 1847, Judge Hulett and General Ellet met at the old Eagle tavern at Niagara, and the latter had the contract for erecting the bridge. During their talk the merits of a cable and basket as an aid to the great work came up, and the service was recognized as possible. What material should the basket be made of? was the question. General Ellet favored wood; Judge Hulett, iron. Calculations showed that Judge Hulett's plan would result in an iron basket 10 pounds lighter than one of wood built according to Ellet's plan. The form of the basket was then quickly decided by Judge Hulett and General Ellet arising from the old-fashioned rocking chairs in which they sat, and, drawing them together, Judge Hulett said "There is the form of the basket."

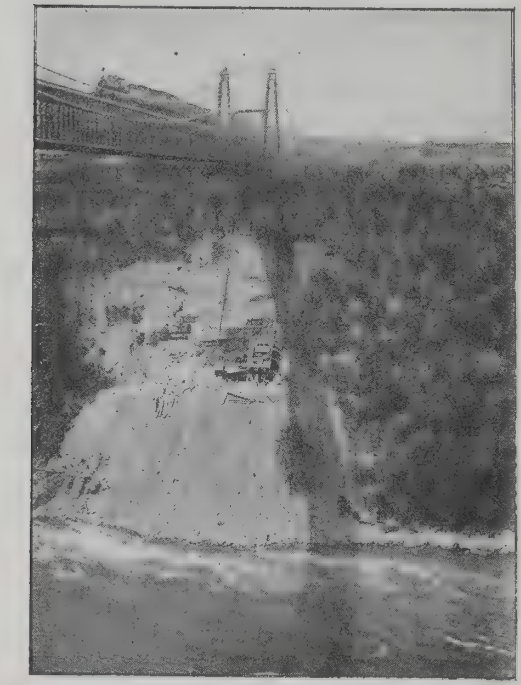

Fig. 1.—Building Concrete Foundation for Canadian Abutment of the New Steel Arch Over the Niagara Gorge.

While this aerial line of 1848 was not intended as a money-maker, it proved to be such, as the charge for transportation over and back was $1 for each person, and some days as much as $125 was taken. The basket is now in the possession of the Buffalo Historical Society.

Years were consumed in the work of building the bridge, and it was not until March 8, 1855, that the first train crossed it. As first erected, the bridge had wood trusses and towers of stone. In 1880 the suspended structure was changed to steel, and in 1886 the stone towers were replaced by towers of steel. The present bridge has a span of 821 ft. from center to center of towers. It is suspended on four cables, the diameter of each being 10¼ ins., and their ultimate strength 12,400 tons. The weight of the superstructure is 800 tons.

Mr. L. L. Buck, M. Am. Soc. C. E., is chief engineer of the new steel arch. Mr. Buck is thoroughly familiar with the suspension bridge and its locality, for it was from his designs and under his personal supervision that the suspended structure and towers were renewed, as above mentioned. It will be recalled that this work was completed without the slightest interruption to traffic, and it has gone down in history as one of the many brilliant things accomplished by Mr. Buck.

This grand new arch will have a span of 550 ft., between the end piers, and a trussed span 115 ft. long will connect it with the top of the bluff. The main span will be formed by an arch with horizontal upper chords. At the skewbacks it will be hinged. Each truss will have a batter of 1 horizontal to 10 vertical. The width between the centers of the top chords will be 30 ft., while between the centers of the rib at the crown the width will be 56 ft. 7¾ ins. From the centers of the skewbacks to the upper chords will be 134 ft., while the centers of the ribs at the crown will be 114 ft. above the skewbacks. On the American side the bed plates of the arch will rest on masonry built on the Clinton limestone, but on the Canadian side it has been found necessary to build a foundation of concrete, work on which is illustrated in Fig. 1. On this foundation the masonry will rest. It will be seen by the illustrations that the abutments are being built about half way up the slope on each side, between the water's edge and the top of the bluff. The ends of the shore span will be hinged to the arch by a pin at the point of intersection of the end post and top chord of the arch, while the shore end will rest on expansion rollers on masonry abutments.

As stated above, the new arch will have two floors or decks. On the upper chords of the arch transverse steel beams will be placed, and between these beams there will be four longitudinal lines of steel stringers. These will be 7 ft. apart and directly under the railway tracks, thus affording double track railway facilities, whereas there is but a single track on the suspension bridge now in use. A steel plate, reaching from end to end of the bridge and from the top of the upper chords to the tops of the ties will cover the ends of the railroad ties and the transverse beams.

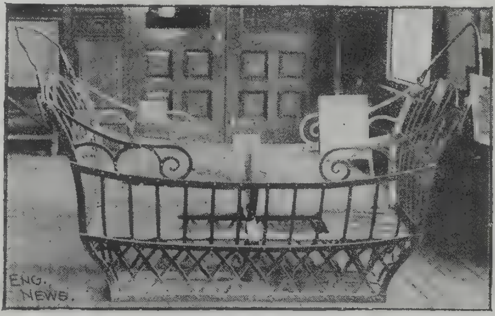

Fig. 3.—Basket in Which Passengers Were Carried Across the Niagara Gorge in 1848.

The ties of the railroad tracks will be 10 × 10 ins. × 10 ft., laid 14 ins. c. to c., and will rest on the stringers. Wooden guard rails 8 × 9 ins., notched over each tie, and secured by bolts, at every third tie, will be placed over the stringers and rest on the ties. Every fourth tie will be of increased length to carry a walk. These walks will be placed outside of each track and between the tracks, a feature especially provided to facilitate the customs inspectors' examination of trains crossing the structure.

The lower floor will have transverse beams and four lines of longitudinal steel stringers laid about 11 ft. apart. The inner stringers will be riveted to the webs of the beams and the inner line to the posts. The I-beams crossing the stringers will extend beyond the trusses and provide support for the sidewalks. The floor of the lower deck of the bridge, including carriage way and trolley track, to the width of 27 ft. will be laid on 4 × 10-in. timbers and planked with 3-in. oak plank laid lengthwise of the structure. Outside of these, and a few inches above the carriage floor, will be the sidewalks of white pine plank.

The material to be used in the bridge will include 5,560,000 lbs. of steel plates and angles in the form of columns, plate girders, braces and struts; 218,000 lbs. of steel castings; 182,143 lbs. of steel eye-bars and pins, and 30,000 lbs. of wrought iron rods and turnbuckles. The arch supports will be steel castings. The specifications provide that the steel for the rollers must have an ultimate strength of from 65,000 to 70,000 lbs. per sq. in.

Fig. 2.—View Looking Up From the Water's Edge on the American Side.

(The masonry in the foreground is the wall behind which is the roadbed for the electric railway which now runs through the gorge.)

The new arch is designed for a load on each track of two locomotives with four pairs of drivers each, and 40,000 lbs. on each pair, followed by a train of 3,500 lbs. per ft. In addition to this may be placed a live load of 3,000 lbs. per ft. on the lower floor.

In erecting this structure the end spans and the first panels and posts of the ends of the arch will be supported on falsework. It is then proposed to connect the end spans with the end posts of the arch, and by means of the approach girders, with the temporary anchorage, when the two parts of the arch will be built out as cantilevers. It is not intended that traffic on the suspension bridge shall stop while the work is in progress, and for this reason the upper floor beams of the arch will be left out until the suspended structure of the new bridge shall be raised sufficiently high to allow the beams to be placed under the upper chords of the suspension bridge. While this is going on, the cables and towers of the bridge may be taken down and removed. Then the old bridge will be shoved to one side far enough to allow the laying of a track on the pair of the new stringers, when the old bridge can be taken apart and the arch completed. During the construction it is likely that wire ropes of good strength and size will be run over the present towers with trolleys attached to carry material out over the gorge to the point of operation.

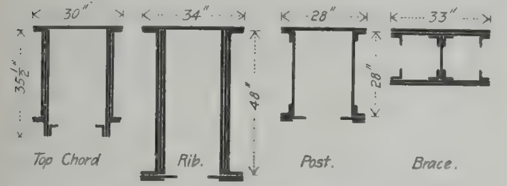
bridge. The stone for the American abutment is being brought from Chaumont, Jefferson county, N. Y., and that for the Canadian abutment from Queenston, Ont., quarries, the concrete being now ready for the stone work. By means of a derrick erected on the north side of the bridge, the huge stones are lowered to the slope below, where they are picked up by another derrick and lowered to the abutment.



Typical Sections of Main Members of Arch.

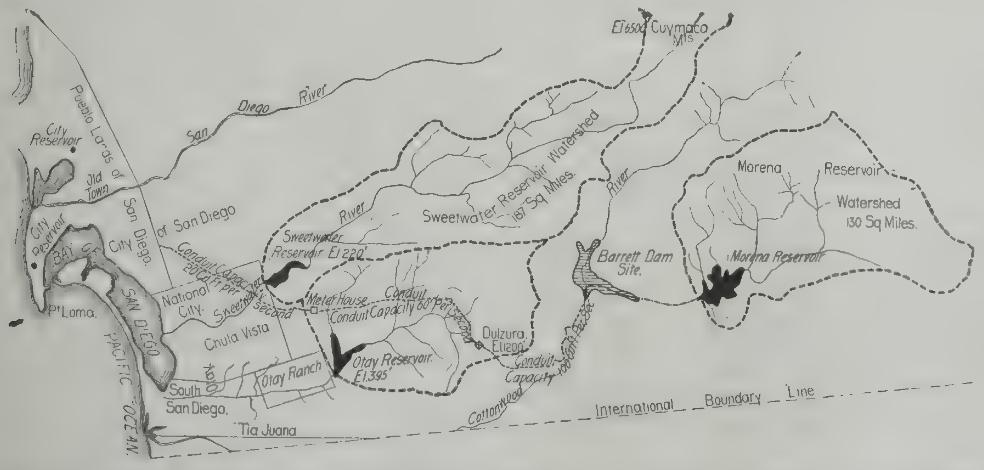
By Fig. 1 it will be seen that on the Canadian side a long trough or chute has been erected and extends from the bridge to the work on the slope. It is through this chute the sand is lowered, and at about the same point the cement is lowered in bags.

◆

THE WATER SUPPLY FOR SAN DIEGO, CAL.

The movement for the municipal ownership of water-works has been strong in California, as elsewhere in the United States, during the past few years. The largest city in California to take decisive steps towards owning the works supplying it with water is San Diego. On June 27, 1896, by 57 votes over the required two-thirds majority, the people of San Diego voted to issue $1,500,000 of bonds for water-works. This sum is to be divided about equally between the work of developing and bringing a supply to San Diego and the work of distributing it within the city limits. The principal interest attaches to developing the supply, as this includes a rock fill dam with an asphalt face, 3,100 ft. above the sea; a storage capacity of 632,448,000 cu. ft., or 4,730,000,000 gallons, above the 30-ft. contour line of the dam; and some 50 miles of conduit, made up of natural rock channels, cement-lined canal, wood and steel pipe.

The city of San Diego had a population of 16,159 in 1890. It has been supplied with water by a private water company since 1873. In 1891 it was reported that the city had leased the private works for 20 years, but this lease seems to have been discontinued afterwards.



MAP SHOWING THE LOCATION OF THE NEW STORAGE RESERVOIR AND SUPPLY CONDUIT FOR SAN DIEGO, CAL.

The $1,500,000 of bonds noted above were voted, practically, as a ratification of and a means of carrying out a conditional contract made with the Southern California Mountain Water Co. on May 9, 1896, for building the proposed new works and supplying the necessary water rights and land.

The contract calls for a daily supply of 1,728,000 cu. ft., or 12,950,000 gallons a day. The gathering area includes about 130 sq. miles of territory east of the city and beyond the drainage area of the great Sweetwater reservoir of the San Diego Land & Town Co., as shown on the accompanying map. The Otay reservoir, also shown on the map, to the south of the Sweetwater system, is already under construction by the Southern California Mountain Water Co. Water from it will be used for irrigating low lands in the southwestern part of the tract, shown by the map. The Otay reservoir will be filled, in part, it is said, from the Morena reservoir, as the new reservoir for San Diego is to be called, a conduit leading to the Otay reservoir from Dulzura Pass, at an elevation of 1,200 ft.

The conduit from the Morena down to the Dulzura Pass is to have a capacity of 100 cu. ft. per sec.; from this point to the meter house, shown on the map, the capacity is to be 60 cu. ft. per sec., and from there to the city line, 20 cu. ft. per sec. The daily capacities for these portions in gallons are about 65,000,000, 39,000,000 and 13,000,000 gallons, respectively. The portion of the conduit between the meter house and the city is not included in the contract for developing a supply. This section of the conduit, with four reservoirs and the distributing mains, is to be under a separate contract, but the Southern California Mountain Water Co. has bound itself, when bids for this work are invited, to submit a proposal of not over $728,000.

The contract between the city and the above company contains no detailed specifications regarding the character of the dam and the conduit to the meter house, but does contain specifications for the balance of the conduit and the distribution system. The conduit from the meter house to the city will be at least 29 ins. in diameter, of wood where under less than 100 ft. head, and where under high pressure of riveted steel. One of the four distributing reservoirs will have a capacity of 5,000,000, another of 2,500,000, and two of 500,000 gallons, each.

The city is given the right to adopt whatever measuring devices it may see fit for use at the meter house. It also has the option of buying an additional quantity of water delivered at the meter house, up to a second 13,000,000 gallons, at any time within 20 years.

Mr. E. S. Babcock, Manager of the Coronado Hotel, San Diego, is president of the Southern California Mountain Water Co., and Harris & Russell are engineers. Mr. E. E. Capps is city engineer of San Diego.

THE STRENGTH OF TIMBER AND A FORMULA FOR TIMBER COLUMNS.

In our issue of Oct. 24, 1895, we printed a table of average safe working unit strains of various timbers recommended by a committee of the Association of Railway Superintendents of Bridges and Buildings, and presented at the Annual Convention of the Association at New Orleans on Oct. 15. The pamphlet copy of the proceedings of the convention, now printed, contains a large amount of interesting matter on the subject of the strength of timber, much of it being a compilation of matter previously published, but also including some new information. Among the latter is a formula for strength of columns derived by Mr. A. L. Johnson from the unpublished results of the government timber tests conducted at Washington University by Prof. J. B. Johnson, supplemented by an examination of previous full-sized column tests. Mr. Johnson also gives a table of unit stresses recommended for various kinds of timber, which is also based chiefly upon the government tests. The formula is as follows. For timber columns with square ends (but not for fixed ends):

$$f = F \times \frac{700 + 15\,c}{700 + 15\,c + c^2},$$

where

f = ultimate breaking unit crushing stress on long column.

c = ratio of length to least cross-sectional dimension.

F = ultimate breaking unit crushing stress on short column.

The recommended values for F are those given under "crushing strength endwise" in the table printed below.

Recommended Values for Unit Stresses of Timber. A. L. Johnson, October, 1895. Ultimate Breaking Stresses in Pounds Per Square Inch.

Species		Modulus of strength at rupture in lbs. per sq. in.	Modulus of elasticity in lbs. per sq. in.	Relative elastic resilience in in. lbs. per cu. in.	Crushing strength endwise lbs. per sq. in.	Crushing strength across the grain lbs. per sq. in.	Tensile st'gth lbs. per sq. in.	Shearing strength parallel to fibre lbs. per. sq. in.
Long-leaf pine	D	7,750	1,440,000	1.30	5,000	645	12,000	500
Short-leaf pine	D	6,500	1,200,000	1.30	4,200	645	9,000	400
White pine	D	4,400	870,000	1.00	3,500	440	7,000	300
Norway pine		5,450	1,132,000	....	3,800	430	....	...
Colorado pine		4,900	888,000	....	3,150	540	....	...
Douglass fir		6,600	1,380,000	....	4,400	500	....	...
Redwood		7,200	452,000	....	3,250	345	....	...
Red cedar		5,000	670,000	....	3,500	750	....	...
Bald cypress	D	5,000	900,000	1.10	3,375	360	6,000	240
White oak	D	6,000	1,100,000	1.25	4,000	1,200	10,000	800

Note.—The values marked "D" were obtained from experiments made by the U. S. Forestry Division. The other values were obtained from various sources, chiefly from the tenth census report, but so modified as to give results comparable with the forestry division values.

These values are for 18% moisture, representing a half dry condition. For modifications of these values for other moisture conditions, and for fuller general description, see bulletin on "Timber Trestle Design," issued by the forestry division.

Mr. Johnson considers his formula as of nearly if not the true theoretical form, and the coefficients are entirely empirical, based upon actual tests. In the table given above the unit values given are for large-size sticks, such as are used in practice. The ultimate strength across the grain is taken as the stress producing an indentation of 37% of the thickness of the compressed stick.

◆

THE NEW IRON DISTRICT IN SOUTHERN RUSSIA.

In a recent number of the Consular Reports is an interesting article on the Iron Industry of Russia, translated from the "Vienna Handels-Museum." It describes the development of the industry in the department of Yekaterinosslav, in Southern Russia, where, since 1887, six large manufactories have been established. In 1893 their production amounted to 322,439 tons, in 1894 to 416,157 tons, and the production for the year 1896, it is estimated, will reach 645,000 tons, or double that of 1893. The iron beds of Southern Russia are very extensive and contain ore carrying as high as 70% of iron. The article also states that "the ore is comparatively free from foreign admixtures; on the other hand its fusibility is not great, about 45% of flux being required to melt it." About 55 lbs. of coal are required for the manufacture of each pood (36 lbs.) of cast iron. These statements about the amount of flux and of coal would indicate either that the statements concerning purity of the ore are not accurate or else that the method of operating the furnaces is uneconomical as compared with that of modern

American furnaces. The coal supply in the immediate neighborhood of the iron mines is abundant, the output in the Doneg basin in one year, 1893-4, amounting to over 5,350,000 tons. Limestone also is found in vast quantities on the spot. Under these circumstances, says the report, it is beyond doubt that the near future will see an immense development of the mining industry in Russia. At present, however, the total product falls short of the requirements, which are constantly increasing, and great quantities of cast and rolled iron are imported from Germany. The report states that there is a favorable opportunity for Austrian iron founders (and for the American founders also, says Consul Stephan), to extend their sales in Russia. The prices for iron charged by the Russian furnaces are so high that, notwithstanding the high duty on cast iron, wrought iron and steel, machine makers find it more profitable to buy imported iron. If, however, the statements given in the report as to the abundance of ore, coal and limestone in the same field, and the increase of production since 1887 are true, it would appear that before long Russia will be able to make all the iron and steel she needs for her own consumption, if in fact she does not even become an iron exporting country.

STEEL LOCK GATES FOR 800 x 100 FT. SHIP CANAL LOCK, SAULT STE. MARIE, MICH.

An illustrated description of the lock chamber, steel gates and power machinery for the new U. S. Government ship lock at St. Mary's Falls, Mich., was published in Engineering News of Sept. 26, Oct. 10, 17, 31 and Nov. 28, 1895. Since that time much additional information regarding the design and construction of the steel gates has become available and is presented here in part as a supplement to the previous articles. This matter should preferably be read in connection with the illustrations published in Engineering News of Oct. 10 and 17, but for the clearer understanding of those who have not these issues the article has been made complete in itself. For the information from which it has been prepared we are indebted to the reports of Capt. H. F. Hodges, Engineer Corps, U. S. A., and of Mr. David Molitor, United States Assistant Engineer, published in the report of the Chief of Engineers, U. S. A., for 1895, and to information received direct from Mr. J. L. Callard, United States Assistant Engineer.

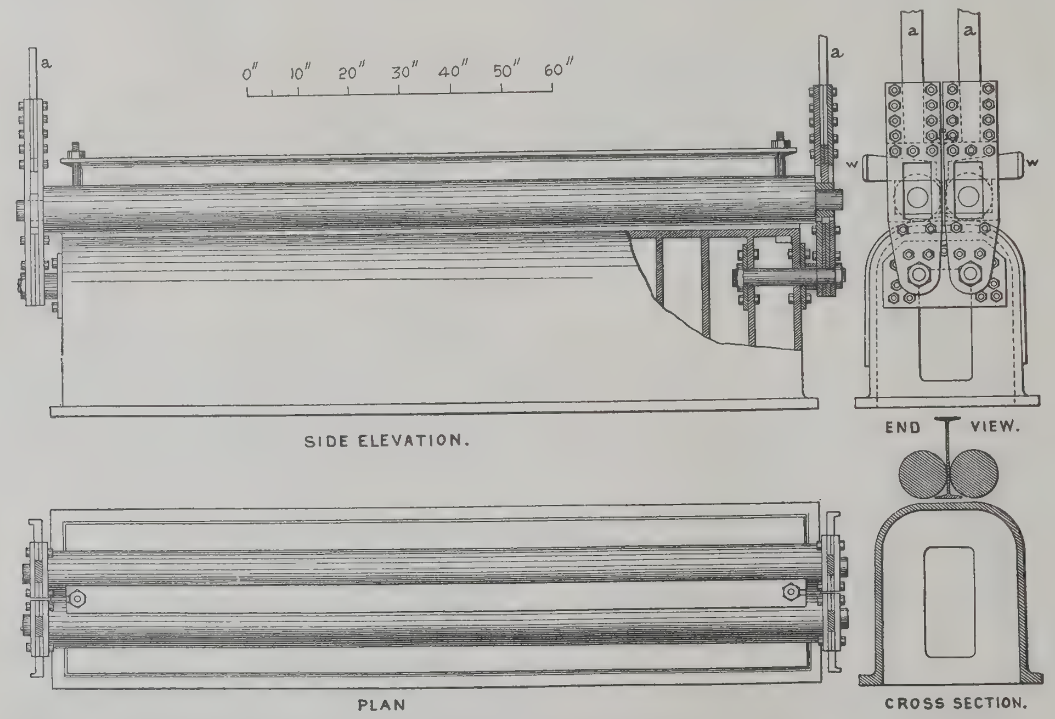


FIG. 1.—APPARATUS FOR BENDING SHEATHING OF QUOIN POSTS FOR ST. MARY'S FALLS LOCK GATES.
Detroit Bridge and Iron Works, Detroit, Mich.

Introductory.—Three sets of locks have been built at the St. Mary's Falls Canal, viz., the flight of two locks built by the State of Michigan in 1855 and now removed; the single lock built by the United States in 1881 and still in use, and the single lock which has just been completed and was built by the United States nearly on the site of the old state locks. The gates of the first locks were of wood and iron and closed an opening of 70 ft. The horizontals were constructed of solid built timber bowstring girders trussed with adjustable iron rods. Each leaf was swung without rollers from a pivot and set of suspension rods passing over a post rising from the masonry at the hollow quoins. The gates of the lock built in 1881 close a clear opening of 60 ft. Their structure is similar to that of the older gates, but the mounting is different, the fastenings being the ordinary pivot, gudgeon and collar, without suspension rods or rollers. Each leaf of the lower lock gate of this lock weighs 76 tons and cost about $8,000.

The new 800 × 100-ft. lock has five sets of gates, viz., an upper and lower guard gate and an upper, intermediate and lower lock gate. Of these the guard gates are used to isolate the lock when it is pumped out and the lock gates are used in passing vessels. The average lift of this lock is 17.61 ft., the depth of water over the sill is 22.24 ft., and the surface of the coping of the side walls is 45 ft. above the floor. It is clear, therefore, that the lower lock and intermediate gates must be of very large size.

Compared with the gates of other great locks these gates have the dimensions shown in the accompanying table. It is evident that a careful study was necessary before fixing upon the design of gates of such size.

Choice of Material.—Preliminary designs were prepared for gates of the kind now in use in the lock of 1881; for composite gates with timber arches and iron sheathing, and for metal gates with and without an air chamber. Estimates based on these designs at the prices of material ruling in 1886 to 1888 indicated that there would be but little difference in the first cost of gates of either material, the advantage lying with the timber, while it was probable that the metal structures would far outlast the others. This superior durability seemed probable from the fact that certain iron gates built in Germany more than 40 years ago are still in service and in excellent condition, while timber gates rarely last more than 25 years.

In this case also more than the usual number of objectionable features attached to the use of a roller to partially support the leaf, since the construction of trucks for such rollers would necessitate a modification of the projected filling and emptying system which was undesirable. Metal gates of the largest size may be constructed so as to carry the weight without the use of rollers, but with timber leaves of such large dimensions it is difficult to obtain the necessary rigidity of assemblage.

Experience in France has shown that, at the present day, leaves approaching the size of those under consideration can be constructed much more cheaply of metal than wood. In the United States the cost of timber is not so great as in France, but it is continually increasing. If the gates of the new lock were to be made of wood to-day they would need to be renewed in about 20 years, when the cost of timber would probably be so great as to compel the use of metal in the reconstruction, while the shape would have to correspond to the masonry and be still designed for the original wooden structure. Thus the shorter probable life of the timber gate, the difficulty in so assemblying it as to carry its great weight rigidly without a roller, and the fear of trouble in future renewal caused the selection of mild steel as the material.

Choice of Type.—Having chosen the material the type of leaf was selected with the view of attaining the greatest lightness and facility of operation consistent with safety. When the gates are first swung or when subsquently the lock is pumped dry, the stresses due to the full weight of the leaf are thrown on its pivot and anchorage. While maneuvering, a large part of the weight may be buoyed up by an air chamber, which is easily constructed in a metal gate; but even then an accidental blow may puncture the sheathing and throw nearly the whole weight onto the pivot and anchorage. It was, therefore, considered necessary to make the latter strong enough to carry the weight in air, and on this account even more than on the score of economy of material in the gate itself, it became desirable to reduce the weight of the leaf to a minimum.

Theoretically, the water pressure on lock gates mitering can be resisted with the least amount of material in the horizontal frames when the latter are in the form of segmental circular arches extending from quoin to quoin and subtending an angle of 133° 33′ 48″, of which each leaf, of course, subtends half. When the lock is 100 ft. wide, arched gates of this curvature will support a given normal pressure with about one-half the material which would be required in the lightest straight gates which can be designed with the same factor of safety.

In practice, with leaves of the span in question, so great a curvature has two objections, viz., it increases the depth of the gate recesses and it increases the tendency of the gate to warp under its own weight when swinging without a roller. By calculation it was found that the theoretical weight of arched leaves of the same span and different rises increases slowly at first and subsequently more rapidly as the radius increases. For example, if the weight of the lighted leaf with a curvature of 66° 46′ be taken as 100, the leaf 40° will weigh 122, while the leaf 22° will weigh 200. It being recognized as desirable to make the gates as light as possible, the type with fully arched horizontals was selected, but it was not pushed to the theoretical extreme on account of the objection to the great curvature.

The number of horizontals to employ was a question requiring consideration. There seemed but two alternatives, viz., to space either the horizontals or verticals closely enough to supply the main supports to the sheathing against local hydrostatic pressure. In the one case many horizontals would be used with a vertical system of less strength; in the other the horizontal strength of the leaf would be concentrated at the top and a vertical system would be used strong enough to receive the water pressure and transmit it to the sill and the horizontal member at the top of the leaf. The large amount of pressure thrown to the sill and the localization of the thrust against the masonry at the top of the hollow quoin are objections to the latter method when the actual load on the leaf is so great and therefore the former method was chosen.

For uniformity and simplicity of construction the same form was adopted for all the gates, although the selection was originally goverened by the great dimensions of the largest ones. The intermediate gate, 43 ft. high, is a duplicate of the lower lock gate. The upper lock and upper guard gates are 26½ ft. high and are duplicates, and the lower guard gate is the smallest, being 25½ ft. high.

Construction.—In Engineering News, Oct. 10 and 17, 1895, quite full drawings of the south leaf of the lower lock gate were published and may be referred to for information in addition to what is given here. This gate is designed to bear the pressure due to 21 ft. of water, and the maximum allowable stress adopted is 9,000 lbs. per sq. in., except in those parts which are most strained by the weight of the leaf, where the fiber stress exceeds this by 1,000 lbs per sq. in., when the leaf is in air.

Briefly described, the leaf is a steel structure having a framework sheathed on both sides with plates. It is curved in plain, the two leaves forming a continuous arch when closed. The upstream and downstream surfaces are portions of cylinders. The clear distance between the sheathing plates is 30 ins. at the ends and 36 ins. at the middle, this splay being given to make the interior more accessible and to allow for variations in the position of the curve of pressure. The body of the leaf is 43 ft. high surmounted by a footbridge 20 ins. high, the top of which is level with the coping of the side walls. The chord of the leaf measured between the centers of the surfaces of contact at the quoin and miter posts is 56 ft. 7.69 ins. The median circle measured between the same, a radius of 77 ft. 3.38 ins., and subtends an angle of 42° 59′ 40″. With the adopted construction the depth of the gate recess from the inmost element to the plane of the face of the lock wall is 8 ft. 7.13 ins. The weight of each leaf in air is 312,000 lbs.

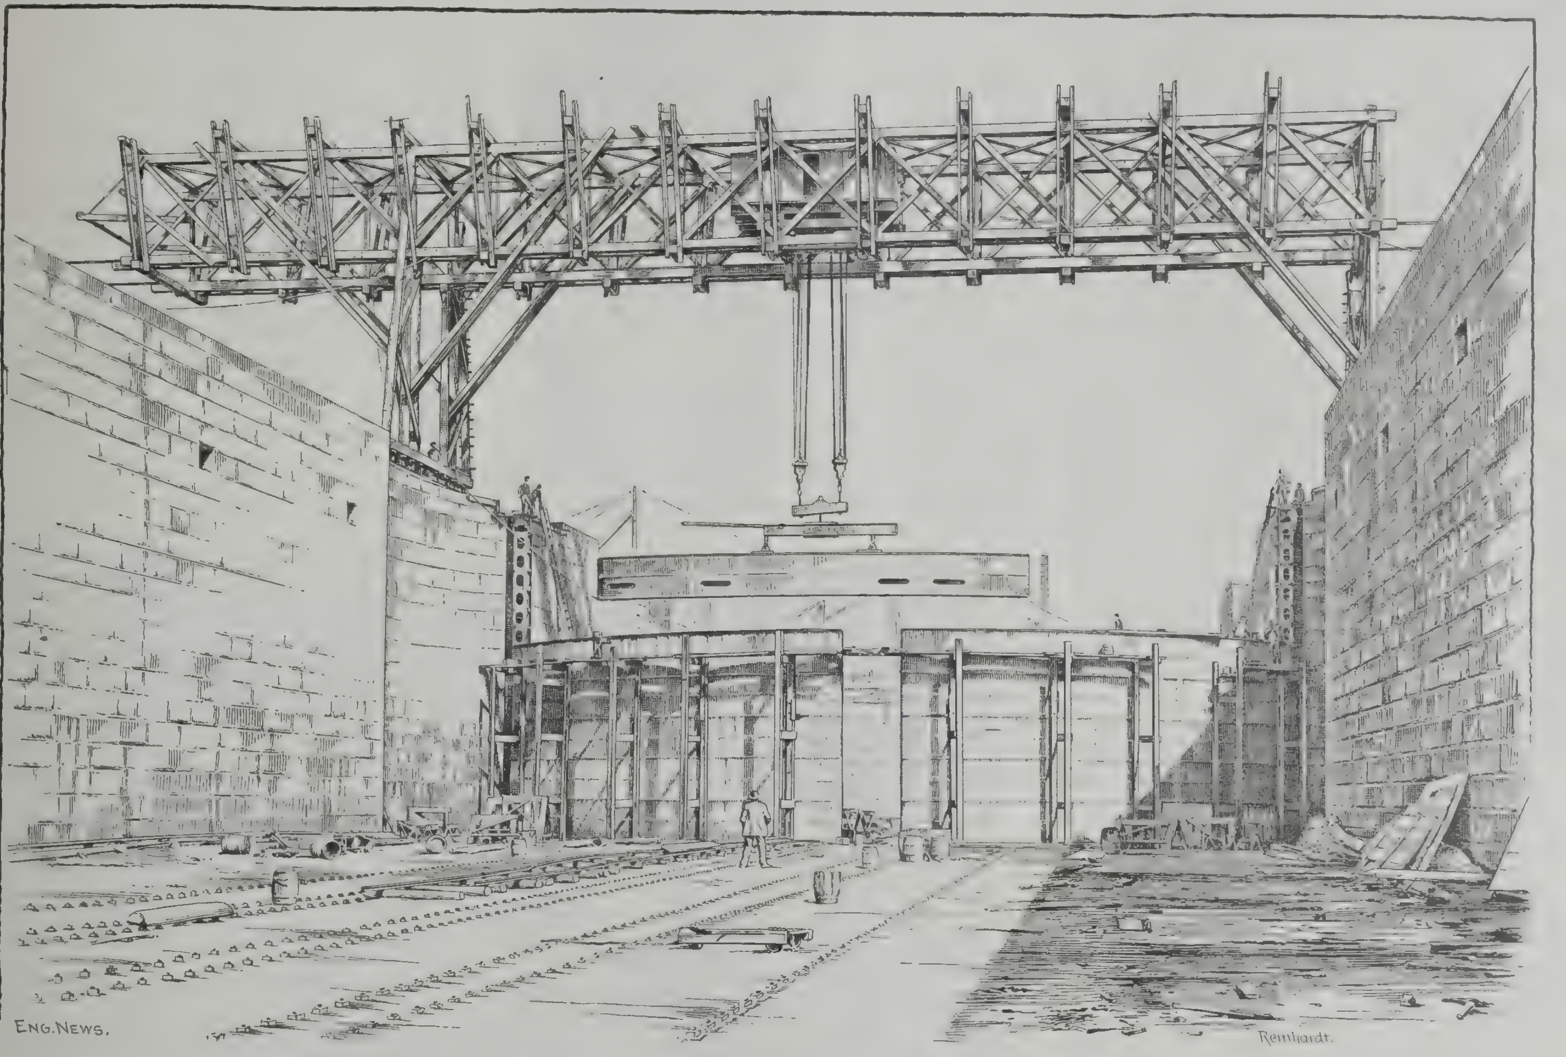

FIG. 2.—VIEW OF TRAVELER ERECTING STEEL GATES AT ST. MARY'S FALLS CANAL LOCK.

The framework of the leaf consists of 18 horizontal arches, the quoin and miter posts, seven vertical frames and a large number of intercostal stiffeners to strengthen the sheathing. The horizontal arches are uniformly spaced in a vertical direction 30 ins. apart, between centers, and are numbered from 1 to 18, beginning at the top. The space between arches 8 and 18 constitutes the air chamber which buoys up the leaf so that its weight in operation will be about 60,000 lbs.

The quoin post is made of ⅜-in. plates so curved in plan that the bearing of the post against the masonry is a plane surface 10 ins. wide. This plane is tangent to two cylindrical surfaces which round off the corners. There is no contact between the post and the hollow quoin until the leaf is completely closed. An oak cushion secures a water-tight joint when contact is secured. At the top of the post is a detachable gudgeon of forged high carbon steel 8 ins. in diameter, and at the bottom is a foot plate of like material having in its bottom a socket bushed with bronze. This socket fits onto a spherical pivot 10 ins. in diameter keyed into a circular bed plate of cast steel set in the lock floor.

The miter post is formed by bending the sheathing around the ends of the horizontal arches. Each holds by means of angles an oak cushion which forms the contact surface 12 ins. wide.

Between the quoin and the miter posts come the vertical frames. These consist of three full frames extending from top to bottom of the leaf and spaced at equal distances horizontally. These full frames divide the leaf into four water-tight bulkheads, each of which is provided with a pump. Between the full frames are four half frames which extend from the top to the bottom of the air chamber only and support its sides against the water pressure. To support the sheathing against local water pressure the intercostal stiffeners are used. These consist of angles extending vertically between the horizontal arches, and spaced to suit the pressure.

The sheathing is attached in horizontal strakes, each 60 ins. wide, except the bottom strake, which is 36 ins. wide. The joints are single riveted, covered on the inside by the horizontal arch angles and on the outside by cover plates. This sheathing performs a complex function; it acts as a web member against vertical shearing forces; it receives the water pressure and transmits it to the frames, and it acts with the frames to resist general structural strains.

In closing these paragraphs on construction a few words need to be said in explanation of the operation of the air chamber. When the leaf is closed and the rising level in the lock presses it against the sill, the bottom of the leaf as well as the vertical surface is exposed to pressure and a tendency to lift the leaf off its bearings is produced. As soon as the level of the water in the lock reaches the top of the air chamber it enters the leaf and thereafter as the water level rises the increasing weight of the water on top of the air chamber counterbalances the increasing pressure on the bottom. As the bottom of the air chamber has an area greater than the top and as the top of the air chamber is 2½ ft. above normal pool level the total upward pressure on the bottom of arch No. 18 exceeds the downward pressure on the top of arch No. 8, and the leaf requires a considerable preponderance of weight over buoyancy when swinging freely in order not to be lifted off its bearings when closed. This preponderance when moving is 22.7 tons at extreme high water and 52.2 tons at extreme low water, while the remaining stability when the lock is full is 5.8 tons.

Shop Work.—The principal features of the shop work arose in connection with the work of assembling and the bending of the heavy plates for the quoin and miter posts.

The posts were assembled in their natural positions with sheathing vertical. Four horizontal cells, i. e., two sections, beginning at the bottom of the leaf were first erected, carefully supported and leveled, and then the reaming and riveting done. The bottom section was then removed, the second section lowered into its place and the third section erected on top of the second section, and this process repeated until finally the top section of the leaf had been reamed and riveted. By this process there was never any excessive height of material at one time. The reaming was done mostly by portable reamers, some driven by compressed air and some by rope transmission. Wherever possible the riveting was done by compressed air riveters.

Several methods were devised and tried in bending the curved plates for the quoin and miter posts but the apparatus shown by Fig. 1

was the most successful. The heated plate was taken from the furnace and, having previously raised the rollers and I-beam sufficiently by drawing the wedges (w), was slipped onto the cast-iron frame. The wedges were then driven, the I-beam screwed down, and then the arms (a) simultaneously lowered to a horizontal position wrapping the heated plate tightly around the planed surface of the former. With this machine the work was done very rapidly and successfully.

Table Showing Dimensions, Cost, Etc., of St. Mary's Falls Lock Gates as Compared with Other Large Lock Gates in America and Europe.

Place.	Clear opening.	Height of body.	Length of chord	Material.	Weight per leaf (tons of 2,000 lbs.)	Cost per leaf.	Date of construction.	Remarks.
St. Mary's Falls Canal:	Ft.in.	Ft.in.	Ft.in.					
800-ft. lock	100 0	43 0	56 8	Steel	157.5	$19,369	In hand	Fully arched, double sheathed.
Lock of 1881	60 0	38 6	35 7	Timber	76.0	8,000	1880	Girders, trussed with iron rods.
Cascade Locks, largest leaf	80 0	54 0	51 4	Steel	158.5	*41,000	In hand	Fully arched, single sheathed.
David's Island	100 0	14 0	118 0	Timber	114.5	14,055	1885	Rolling caisson spanning lock.
St. Nazaire	82 0	33 6	44 11	Iron	...	30,000	1874	Plano convex, double sheathed.
Havre, France: Bellot	98 6	35 9	53 4	Iron	171.0	26,000	1886	Vertically framed, double sheathed
Transatlantic	100 0	34 9	56 7	Iron	175.0	31,000	1884	Vertically framed, double sheathed
Transatlantic, old	100 0	32 2	56 7	Timber	149.0	40,000	1861	Plano convex, back fully arched.
Dunkerque	69 0	27 9	38 4	Iron	49.0	6,500	1880	Vertically fr'm'd, with air chamber
Victoria Docks, old	80 0	31 0	46 4	Iron	110.0	10,800	1858	Fully arched, double sheathed.
Barry Dock	80 0	46 4	48 0	Iron	254.0	......	1889	Both faces curved, double sheathed
Avonmouth Docks	70 0	45 0	42 10	Timber	115.0	......	1877	Fully arched.
Manchester Canal: Eastham l'k	80 0	45 5	45 9	Timber	280.0	......	1893	Girders strengthened, iron plates.

Erection.—The quoin post of each leaf was built up complete with foot plates at the shops and shipped in one piece. The horizontal arches were built up as complete girders and each leaf was shipped in horizontal sections, composed of two such girders connected complete, with the cover plate that connects each section with the next section above riveted in place at the upper outside edge of each section, and the two angle irons and horizontal web plate similarly riveted on the inside, so that in erecting, when one section was placed on top of the other, the outside sheathing was simply dropped down between the cover plate and the corresponding angle irons. The riveting necessary to be done in the field was that of riveting each section to the quoin post, and one horizontal row of rivets on both sides of the gate between each section. The angle irons for holding the vertical wooden cushions in place at the toe were riveted to the gate after each leaf was erected.

After erection, the air chambers were calked water tight and subjected to a test of 25 lbs. per sq. in., hydraulic pressure, before being painted. All accessible joints were calked with a patent calking machine operated with compressed air. The calking was a very tedious and expensive operation. Fresh air had to be supplied to the men while working on the inside of the gates. This was accomplished by means of tapping the main air pipe leading from the air compressor at the electric light station to the drills working on the lock floor. The work of erecting the gates is not quite completed. The intermediate lock gate is yet to be calked and tested, and it together with the lower lock gate are not yet painted. The work of erection was begun in July, 1894, and was continuous to November 5, 1895. The average number of men per day engaged on the work during that time was 19. Fig. 2 shows the traveler for handling the section of the gates during the process of erection. The gates were shipped by rail and unloaded on the north side of the canal. A special derrick had to be erected alongside the railway for unloading the sections, and a tramway laid from there to and along the north side of the lock. The maximum weight of a section was about 17 tons. Each half of the upper and lower guard gates and the upper lock gates weighed approximately 100 tons, and those of the lower lock and intermediate gates, 175 tons each. The following is the approximate weight and cost of the gates:

2,404,657	lbs. soft steel at 5.9 cts. per lb.	$141,874.76
119,168	" high steel at 27¼ " " "	32,473.28
36,167	" cast steel at 9¼ " " "	3,345.45
8,665	" cast iron at 6 " " "	519.90
5,322	" phosphor bronze at 35 cts. per lb	1,862.70
7,215	ft. B. M. oak timber at $60 per M.	432.90
28	pumps and fittings	2,100.00
	Total	$182,608.99

The following are some of the principal weights and dimensions of the gates, which are collected here for easy reference:

Angle between chords of leaves when closed	170°	20′′
Clear width of lock	100 ft.	..... ins.
Width between centres of abutting surfaces in hollow quoins	105 "	4.81 "
Rise of median line measured from line joining above centers	20 "	9.08 "
Height of body of gate	43 "	..... "
Radius of median circle	77 "	3.38 "
Length of median circle developed	57 "	11.90 "
Length of chord	56 "	7.69 "
Weight of swinging part in air	156.0 tons	
Manoeuvering weight, air chamber immersed	22.7 "	
" " mean stage	37.9 "	
" " lowest stage	52.2 "	
Remaining stability, lock full	5.8 "	
Total thrust against masonry	1,650 "	
Horizontal pull on gudgeon in air	100 "	

The contractors for the gates were the Detroit Bridge & Iron Works, Detroit, Mich. All the soft steel was furnished to this firm by the Carnegie Steel Co., and the forged and cast steel by the Midvale Steel Co. The machining of the forged and cast steel was done by the Harlan & Hollingsworth Co., of Wilmington, Del.

◆

A SPECIAL SHEARING MACHINE for cutting up old boilers into scrap is in use at the famous Horwich works of the Lancaster & Yorkshire Ry. The machine was built by De Bergue & Co., of Manchester, and it is stated that by its aid three men can cut up a steel locomotive boiler in an hour.

TESTING MACHINE OF 200,000 LBS. CAPACITY FOR THE UNIVERSITY OF NEW YORK.

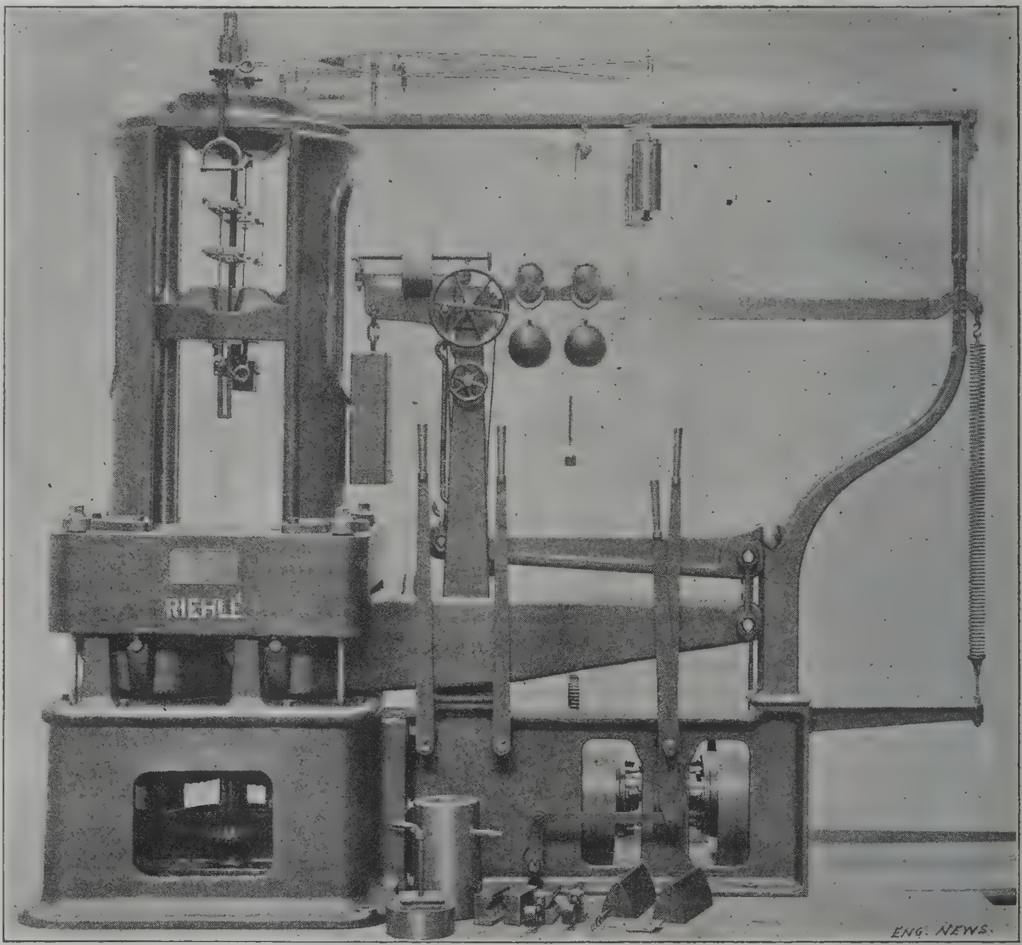
We illustrate herewith a new testing machine recently built by the Riehle Bros. Testing Machine Co., of Philadelphia, for the University of New York, in which are embodied a number of late improvements in machinery of this class, including the automatic recording attachment invented by Prof. Thomas Gray, M. Am. Soc. M. E., of Rose Polytechnic Institute. The machine was presented to the Engineering Department of the University by one of its undergraduate students.

The machine is 8 ft. 10 ins. high over all, and occupies a floor space of 3 ft. 7 ins. × 9 ft. 9 ins. Its shipping weight is 12,000 lbs. It will take tensile specimens up to 30 ins. in length, 2½ ins. diameter and 3 ins. square, transverse specimens 36 ins. long × 12 ins. wide, and compression specimens up to 24 ins. high. The various speeds obtainable are such that the head may be moved at 1-12, ¼, ⅓, ¾, 1, 2¼, 3¼, or 9 ins. per minute. The last speed, however, is not used for testing, but merely for setting the head. The extreme motion of the head is 2 ft. 6 ins.

The general construction of the machine will be evident from the engraving, but a few words of explanation may aid the reader. The top or fixed head is a steel casting resting on heavy columns, which are carried on the weighing table to which the name-plate is attached. The table rests on the knife-edges of the two main weighing levers, which transmit the pressure to the intermediate lever, which is in turn connected to the weighing beam.

The moving head is raised and lowered by two large vertical screws revolving in brass nuts secured to the head. The thrust bearings of these screws consist of hard steel balls rolling between the circular grooves of parallel plates. Spur-gears on these screws driven by a train of gearing leading to the driving pulleys effect the turning of the screws. Change of speeds or reversal of motion is effected by the hand levers seen in the cut, which operate clutches.

The apparatus seen at the top of the machine is the Gray automatic recording apparatus, which



TESTING MACHINE OF 200,000 LBS. CAPACITY, WITH GRAY AUTOMATIC RECORDING APPARATUS.
Built by the Riehle Bros. Testing Machine Co. for the University of New York.

gives an autographic record both of the elongation within the elastic limit and of the total elongation up to the point of rupture. Briefly described it consists of two clamps fastened to the piece undergoing test and connected to a series of levers which magnify the elongation or compression of the specimen from 50 to 100 times, and move a pen up or down on a rotating drum, seen in the figure directly over the scale-beam. A detailed description with illustrations of this apparatus will be found in a paper by Prof. Gray, read before the American Society of Mechanical Engineers and published in its "Transactions," Vol. XIII., p. 633. It is also described in the "Digest of Physical Tests" for January, published by Frederick A. Riehle, Philadelphia.

A machine identical with the one illustrated, except that the Gray recording apparatus is omitted, has just been placed in the Washington gun factory of the U. S. Navy.

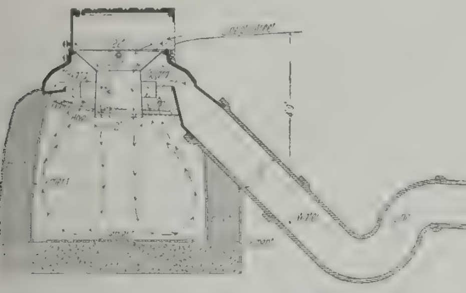
THE HERSHBERGER CATCH BASIN.

A catch basin especially designed to prevent blocking at the entrance while at the same time retaining all floating and suspended matter, is shown by the accompanying illustration. The water and matter carried by it enters the catch basin through a central inlet tube. The heavier dirt sinks to the bottom, and as the water flows to the sewer the lighter material is retained by the bottom and edge of the overflow channel and by the guard.



The Hershberger Catch-Basin. Made by the Bloomsburg Car Mfg. Co., Bloomsburg, Pa.

The overflow channel, or gutter, for the basin shown, is 5 ins. wide, 1 in. deep, opposite the outlet pipe, and 6 ins. deep at the outlet pipe, the bottom sloping towards the outside. The circular guard is attached to the inlet tube by means of three iron braces. Two holes, one of which is shown in the illustration, each 1 × 1½ ins., pierce the inner side of the gutter. They are designed to lower the water in the basin 5 ins., after the surface flow into the basin ceases, thereby lessening the danger from frost and reducing the amount of water to be bailed from the basin into the overflow channel when it is desired to clean the basin.

No bars are placed across the inlet, it being desired that all rubbish shall enter the basin. It is claimed by the inventor that the combined area of the space at the guard is more than double the area of the usual entrance to basins and it is about six times the area of the discharge pipe. Special advantages are also claimed for the frost resisting powers of the basin.

The device was invented by Mr. Jos. Hershberger, Plymouth, Pa., and is now being made and put on the market by the Bloomsburg Car Manufacturing Co., of Bloomsburg, Pa. About 60 of the basins are now being put in at Binghamton, N. Y.

HEATING A COTTON MILL FROM THE HOT WELL OF A CONDENSING ENGINE.

The following description of a novel system of mill heating is taken from a paper read by Mr. Geo. W. Weeks, agent of the Lancaster Mills, at a recent meeting of the New England Cotton Manufacturers' Association, and describes the system in use at those mills. We reprint the abstract from the "Providence Journal," and may remark that while the so-called technical matter published in the ordinary newspapers is apt to be worse than useless, the "Journal" is notable for the excellence of its articles on engineering subjects:

The Lancaster Mills are four stories high and have a basement, and are heated from the water discharged from the hot well of a compound engine driving the mill, and the air is forced through the heater and flues by the flywheel. A small engine and blower are used nights and Sundays when the large engine is not running.

The ordinary Corliss flywheel forced sufficient air for this purpose without alteration (it was found that the air pressure in one of the Corliss wheel pits equalled 1½ ins. of water), but the wheel of the engine used in the mill being made with arms so shaped as to pass through the air with the least resistance, it was necessary to add "wings" to them. This wheel is 16 ft. in diameter and runs at a belt speed of 4,000 ft. per minute. After the wings were attached there was obtained a movement of 8,000 cu. ft. of air per minute through the flues and mill with an expenditure of 3 HP., as shown by the indicator.

The air is taken mostly from the basement, where it enters from out-of-doors and largely from the connecting boiler house.

The heater is situated in the air duct leading to the flue, and consists of eight sections, each 42 ins. high by 28 ins. wide, with 204 ½-in. pipes, each 90 ins. long These sections are connected by pipe with the hot well, and so arranged that the end covers and diaphram causes the hot water to flow by gravity through half of the pipes in one direction and return through the other half, and then continue through the other sections in the same manner, and discharging where the air enters.

Small pipes were used in order to obtain the largest amount of heating surface in a given space, but as there is more heating surface than is needed, it would have been better, perhaps, to have used larger and fewer pipes so as to offer less resistance to the passage of the air.

With water from the hot well at 115° F., the air is heated to 100° F. In one test air was taken directly from out of doors, at a temperature of 26° and sent to the mill at 107°, with water taken from the hot well at 123¼° and discharged from the heater at 97½°. In practice the air is heated to within about 10° of the water used.

While heating the mill in December, before the large engine was started, the fan engine was run, exhausting the steam in the same heater. After the large engine was started, the fan was driven by belt from this engine, using hot water from the condenser of the heater, and while the walls were still wet, the mill having just been completed, with only a few looms in operation, 12,000 ft. of air per minute was forced into it, this being sufficient to heat it while in that condition. This required 8.81 HP., as shown by the indicator on the engine. As soon as the "wings" were put on the arms of the flywheel, the mill was heated with 8,000 cu. ft. of air per minute, as the looms were nearly all then in operation, and that was sufficient. It took 3 HP. only to furnish this air from the flywheel.

The blower was not arranged to be run at a speed to force 8,000 ft. per minute, but judging what it would take from the 12,000 ft., it would doubtless require 5¾ HP. to force 8,000 ft., or nearly double that required by the flywheel.

The use of the vapor on its way from the cylinder to the condenser, to add any heat needed to the air after passing the water heater, was suggested, but was not adopted, as the temperature at this point is only about 134°, while the weight of water in this vapor is very small as compared to the weight of water in the hot well, and this heater being a part of the condensing apparatus, would have to be absolutely tight, and as a consequence be rather costly. So, as the vapor was not utilized, a supplementary heater made exactly like the water heater was placed in the air duct between the water heater and the mill, taking the steam from the receiver between the two cylinders of the compound engine to heat it. This heater also takes the exhaust steam from the fan engine nights and Sundays. It was found that no steam was required in this heater while the mill was in operation, except in extremely cold weather, and last winter none at all was used in it.

It requires about double the heating surface to heat with water that it does to heat with steam, but as water heaters have to sustain no pressure, they can be furnished for a very little more than steam heaters made in the usual way.

Hot or cold water can be showered into the duct in the usual way when desired. When the weather becomes warm enough, so that no heat is required in the mill, the water from the condenser is turned off. and the engine flywheel continues to force the same amount of air through it for ventilating and cooling, and for this latter purpose cold water can be turned through the pipes in the same manner as water from the hot well.

During the time this plant has been used, it has required no repairs and has demonstrated that it will heat and ventilate the mill during the running hours with no expenditude for steam or power beyond the 3 HP. added to the engine as stated; that 100° temperature is sufficient to satisfactorily heat the mill, and that the air can be heated to this temperature, with water from the hot well with no loss of power, and the experiments tend to show that it is more economical (when the uptakes are built into the walls) to send a larger amount of air at a lower rather than a smaller amount at a higher temperature. Air heated to 97 7-10° at the heater is delivered to the fourth story at 94½°, showing a loss of only 3 2-10°, while the air at 124° at the heater was delivered at the fourth story at only 113°, showing a loss of 11°.

Much of the steam used to run the small blower engine, immediately after shutting down at night, and before starting up in the morning, is obtained without extra cost, as considerable of this would otherwise be blown off from the boilers at these times.

ROAD BUILDING IN LANCASTER, MASS.*

By Harold Parker.

The character of the country within the limits of Lancaster is favorable to the building of roads, as they can be easily drained. The soil is, in many places, composed of clean gravel, which, when properly selected and spread, will make a satisfactory road.

The town maintains nearly 100 miles of public highways, and expends for this purpose about $10,000 a year. New roads are constructed under special appropriations. The above amount is sufficient to keep all the roads in good condition, if they should be once made good. Nearly all the roads have been reconstructed within the past few years at considerable expense; and this has reduced materially the annual cost for maintenance, and made it possible to keep in good order a large number of routes and highways. This is mentioned to show that the sentiment of the people at large is changing in favor of permanent improvements.

The conditions are those of an ordinary country town. with the addition perhaps of the increased hauling of stone and wood to Clinton. There is also a very large amount of pleasure driving and bicycling.

The roads are classified roughly into three grades:

1. The main street and thoroughfares leading from it. The main street is a long road lined with houses, and so much used that the best gravel, spread in the ordinary way, will not answer except in summer. The following method has been successfully used: The roadbed was prepared with care both as to its crown and grade, stones about 4 to 5 ins. thick were placed on this, with the smaller part up when possible; on this were dumped smaller stones of nearly uniform size, and then evened off to give a surface corresponding with the finished cross section of the road; on this surface were placed still smaller stones which had been screened in the pit. These should be thoroughly rolled with a heavy roller and covered with a thin layer of clean gravel, which should also be rolled again after being thoroughly sprinkled. The objection to this road is that the gravel pounds up into powder, and this makes dust in dry weather and mud in wet. The cost of this road finished is from 30 to 35 cts. per sq. yd., which includes the cost of moving the old roadbed where necessary. The crown of this road is 1 in. in 2½ ft.

2. The roads outside the main line of travel. These are the ordinary gravel roads, and are made of the best selected gravel within reach. The larger stones are removed with a fork by a man placed on the cart while loading. Under the same conditions the gravel is screened. All cobble-stones collected either in the pit or elsewhere are used in road foundations and are covered by gravel. In this way all the roads are gradually getting stone foundation. Treated in this way, they stand up very much better while the frost is coming out in spring and are more easily repaired. In repairing in spring, where the roads are rutted, the road machine or scraper is used. Where the ruts are merely a displacement of the gravel, the scraper is made use of to replace it and remove the rut, but care is taken not to cut out a gutter or into the surface of the road in any way. A rake and shovel are then used, the surface is made even, and all loose stones, sods, and worn-out material are carefully removed; this refuse matter is dumped on the road side in two places, smoothed off and covered with loam on which grass readily grows, and this adds to the safety of the road as well as improving its looks. Particular care is used to prevent the grass from choking the water-way by the road side.

3. The unfrequented roads used mainly for hauling wood from wood lots to market and for pleasure driving in summer. Very few communities can do more than keep such roads good in summer, or from the time the frost is out of the ground in the spring until it freezes up in winter. The main thing to do is to keep as smooth and perfect a surface as is possible, fill up ruts as soon as made, remove all material that will interfere with the immediate escape of water, and all stones. In this case a road scraper can be used to great advantage, provided it is followed up at once with rake and shovel. The edge of the sod on road sides is cut with care, a line being used in order to get it straight, and offer as little obstruction to the passage of water as may be. Men are constantly employed in removing all loose stones from the roadway, which are carried to a point convenient for future use and are so piled that stones of the same size are placed by themselves. In this way the roads are gradually improving.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32*d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

We wonder how many mills and factories there are in this country in which the workers of all grades, from the manager down to the errand boys, are sweltering and suffering in these hot summer days, while just beside the mill there flows a stream of cool water. We wonder how many times in such mills men have looked out of the windows in hot August days and envied the fishes in the river below.

Probably thousands or tens of thousands have done this, and it is safe to say that quite a number must have had at least a wish that it were possible to distribute some cool breaths from the river through the hot stuffy rooms of the mill. And now it appears that up in New England some one has had the courage to break away from beaten paths and established precedents and actually do what thousands have wished were possible. He has done it moreover by methods and apparatus so simple that the wonder is that they have not been generally applied before.

In another column of this issue we print a brief description of this interesting new departure. Briefly told, it is a blower system for heating and ventilating, in which the pipes of the heater are filled with water from the hot well of the condensing engine instead of with steam. Of course, in hot weather it is a simple matter to force cold water from the river through the pipes instead of the hot water, and thus to distribute cool air instead of warm air. Another notable feature of the system—of course not an essential one—is the use of the fly-wheel of the main engine as a blower. Everyone who has stood near a great fly-wheel knows what a powerful blast it creates. The designer of this system has had the common-sense to utilize this to circulate the air over the heating pipes and through the conduits which distribute it to the various rooms of the mill.

It appears to us that there are some excellent features in this novel plant. In the first place we have the fuel economy of a condensing engine, combined with the economy due to the use of the waste heat of the engine for heating purposes, the same as when exhaust steam is used. It must be borne in mind that there is just as much heat in the water from the hot well, as there is in the steam that enters the condenser. It is at a lower temperature it is true; but to offset this it gives up its heat more readily, and as a heater using water does not operate under pressure it can be made very cheaply. By the use of the fly-wheel as a blower, not only is the cost of the power to run a separate blower, by a belt or a separate engine saved; but the cost of attendance and repairs, always apt to be heavy on machinery of this class, is also saved.

We regret that we have not yet been able to learn the name of the designer of this plant so as to give him the credit that is his due in publishing the description. It appears to us a most creditable piece of mechanical engineering, and one which could be studied with profit by any one interested in the problem of mill heating and ventilation.

◆

A correspondent calls our attention to the fact that our note of last week, in which we referred to Manhattan Island as the only place in the United States where the erection of overhead wires for electric railways is forbidden, is incorrect, as in Washington, D. C., a Congressional statute now forbids the erection of trolley wires. It is true that two street railway companies in Georgetown still use overhead wires; but their systems were built before Georgetown was made part of Washington. Our correspondent sends also the following additional note on the operation of the electrical conduit railways in Washington:

> The portion of the street railways operated within this city have horse, cables or underground electric systems. Congress seems to be firmly insistent on this policy. At the last session it authorized an experiment by one of the street railway companies in the use of compressed air motors, but required that in the event that system should not prove satisfactory to the municipal authorities that the company shall substitute an underground electric system.
>
> The underground systems in use here seem to give full satisfaction in their mechanical operation, and are not more objectionable in other respects than other street railways.

◆

The amended specifications under which Jersey City is for the sixth time inviting bids for a new water supply, noted briefly in another column, have been improved in some particulars, but still shut out all real competition for furnishing a gravity supply, and render the reception of bona fide bids for filtered water very unlikely. Under the new specifications the city reserves the option to purchase the works only at the end of each of the first three five-year periods of the contract, instead of at any time during the contract, as has heretofore been the case. This is in some respects a good change, as the contract will thus be surrounded with less uncertainty for the contractor. Another feature that might prove advantageous to the city is the giving of an opportunity to bid on delivering a part of the gravity supply to high and a part to low service, instead of all of it to either one or the other.

We are pleased to see that the filtration specifications are more liberal and reasonable than heretofore, though still requiring the construction of a pumping plant and force main to deliver the filtered water to the city reservoir and giving only three weeks or so for the preparation of bids. The standard of purity, it is interesting to note, omits the requirement that the contractor shall name the amount of chlorine that the filtrate shall contain, and adds one for the number of bacteria, both most sensible and excellent modifications. But the contractor is still required to guarantee the amount of nitrates in the filtered water, which, as we explained in our issues of April 30 and May 14, is a curious provision, to say the least. The filtration specifications appear to be drawn broadly enough to permit bids on any system until the specifications for the standard of purity are reached. These are so framed as to practically exclude mechanical filtration, or any system except slow sand filtration. Under the latter process contractors are left entirely free to design their plant as they see fit, instead of being limited in certain details, as before.

THE GRADE CROSSING COLLISION AT ATLANTIC CITY.

The most serious railway disaster that has occurred in this country for eight years, took place at a grade crossing of the Pennsylvania and Philadelphia & Reading railways, about two miles from Atlantic City, N. J., at 6:50 p. m., July 30, resulting in the death of 46 persons and the injury of about 60. The accident is the most fatal that has ever resulted from a grade-crossing collision, so far as our search of the records shows, and is exceeded in the number of its casualties by only five railway accidents that have ever occurred in this country.

The following account of the circumstances in connection with this terrible disaster we have gleaned partly from the very full newspaper reports which have been published, but chiefly from the reports of the Coroner's investigation, now in progress at the time this is written, and from facts reported direct to us by an engineer who visited the site of the disaster a few hours after the occurrence.

The Pennsylvania line, known as the West Jersey & Atlantic R. R., is a single track road, running from Atlantic City northwest and closely paralleling for a distance of several miles across the swamps the double track line of the Philadelphia & Atlantic City R. R., operated by the Philadelphia & Reading Co. The two lines cross at grade at a point just outside the limits of Atlantic City, as shown on the accompanying map, and just beyond that point the West Jersey line joins the tracks of the Camden and Atlantic R. R., also a Pennsylvania line.

The crossing is at an angle of about 15° and is protected by an interlocking machine operating home and distant signals on both lines, but with no derailing switches. The home signals are 197 ft. from the crossing on the west side, from which direction trains approach at the highest speed, and 107 ft. on the Atlantic City side. The distant signals are 1,050 ft. from the crossing, on the west side, and 950 ft. on the other side. Track instruments operating electric annunciators in the tower are placed 5,227 ft. distant from the crossing on the west side, and 5,066 ft. on the Atlantic City side.

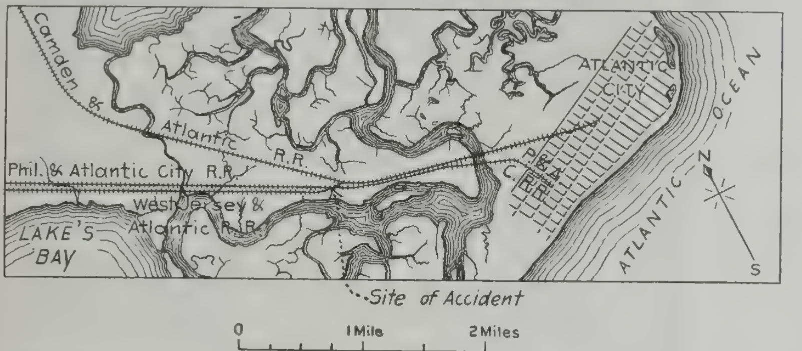
The crossing was established in 1886, under an agreement dated June 18, 1886, under which the Pennsylvania, as the company desiring to make the crossing, assumed the expense of its construction and also of its maintenance. The rules adopted for the use of the crossing and agreed to by the Superintendents of both roads, Aug. 11, 1886, were as follows:

> All engines and trains must approach the crossing carefully, prepared to come to a full stop at a distance of 150 ft. from the point of crossing, unless the proper signal for passing is displayed by the signalman in charge.
>
> In case of an engine or train approaching either crossing upon both roads at or about the same time, priority in the right of passage will be regulated as follows:
>
> 1—Passenger trains as a class.
> 2—Freight trains as a class.
> 3—All other trains as a class.
> 4—Engines without trains as a class.
>
> But as to each class the trains or engines of the P. & A. C. R. R. will have priority over the trains or engines of the W. J. & A. R. R. at the crossing north of Atlantic City, and the trains or engines of the W. J. & A. R. R. and C. & A. R. R. will have priority over the trains and engines of the P. & A. C. R. R. at the Baltic Avenue crossing, Atlantic City. No unnecessary detention to be caused to the trains of either road.
>
> The signals used will be the Semaphore Distant and Semaphore Home at the crossing north of Atlantic City, and the Semaphore Home at the Baltic Avenue crossing, Atlantic City.

The instructions as to signal indications which followed the above are merely those in practically universal use.

The events at the time of the accident were as follows: An excursion train, made up of a locomotive and six cars, heavily loaded, left Atlantic City, on the West Jersey road, about 6:30 p. m., and while crossing the southbound track of the Philadelphia & Atlantic City line at the above junction, it was struck between the first and second cars by an express train on that track. The locomotive demolished the second, and the third cars of the excursion train and the two following cars were telescoped more or less by the collision. It was in these four cars that practically all the casualties occurred. The locomotive and baggage car of the Reading train were wrecked and the engineer was instantly killed. The passenger cars of this train did not leave the track and their occupants were not injured.

After the accident the signals were found to be set to give a clear track for the West Jersey train, but both the home and distant signals of the Reading were at danger. The day towerman, Nicholas Long, testified before the Coroner's Jury that he left the tower in the charge of Geo. Hauser, the night towerman, at 6:40 p. m., and all signals were then at danger. Long had gone but 800 ft. from the tower when he heard the Reading train whistle and saw it coming a half mile away. At the same time he saw that the West Jersey train had the clear signals and was moving slowly toward the crossing. He watched, expecting to see the Reading train stop, but instead came the collision. He then went back to the tower and verified the position of the West Jersey signals. The distant signal on that road had then been thrown to caution behind the train, as is customary.



RAILWAYS IN THE VICINITY OF ATLANTIC CITY, N. J., SHOWING SITE OF GRADE CROSSING DISASTER OF JULY 30.

It will be apparent that the only question as to the responsibility of employees for the accident is as to whether the engineer of the Reading train ran onto the crossing in disregard of the warning of both distant and home signals, or whether Hauser, the night towerman, may have given a clear signal to the Reading train, and afterward changed the signals in the face of the approaching train to give a clear signal to the other road. It must be said that the evidence thus far presented appears to show very strongly that the former supposition is the correct one, and that the dead engineer disregarded both signals, and thus caused his own death and that of nearly fifty others. His train was a fast express train and was accustomed to the right of way. The other train was a heavy excursion train moving at a slow rate of speed. The towerman had both approaching trains in full view. If he gave the Reading express a clear signal when it was so near the crossing as to call the engineer ahead, he would not have had time to then change the signals so as to bring the slow moving West Jersey train on to the crossing in advance of the Reading. To put the case still more clearly, the Reading train must have approached the crossing ordinarily at a speed of 40 to 60 miles per hour. (It is scheduled to make the run from Philadelphia to Atlantic City, 55 miles, in 65 minutes.) The West Jersey train, according to various witnesses, moved slowly up to and on the crossing under clear home and distant signals. Of course, while the signals on that road stood at clear it was impossible for the towerman to have given a clear signal on the other line. Again, the day operator, Long, testified that if he had been in the tower he should have given the Reading train the right of way, and further that he had not stopped a Reading express train for three years. Evidently, then, it was an exceedingly unusual thing for the engineer of the Reading train to find the signals against him at this crossing. Experience has shown that habit is a most powerful factor in influencing men's actions, and the evidence seems overwhelming that the engineer approached this crossing at high speed, expecting to find it clear, as he had hundreds of times before, and in a moment of absentmindedness, he failed to notice and to realize the warning of the signals until it was too late to stop his train. We have said that he approached the crossing at a high rate of speed. The schedule time compelled fast running on the open road. The train left Camden 2½ minutes late and had made up 1½ minutes of this when it passed Pleasantville, three miles above the scene of the collision. But, although the train doubtless approached the distant signal at high speed, it is certain that its speed had been materially reduced when it struck the other train at the crossing. Had this not been the case the locomotive would have, in all probability, cut right through the other train, and it did not do this, but was itself diverted and thrown into the ditch without crossing the West Jersey track. Again, had the Reading train been moving at high speed, its cars back of the baggage car would, in all probability, have left the rails, and some casualties would have occurred to their passengers.

Since the above was written we have received the testimony given before the Coroner's Jury on Aug. 4, when Hauser, the towerman on duty at the time of the collision, gave his evidence, and the conductor, brakeman and fireman of the Reading express train and the engine crew of the West Jersey train were examined. The testimony of all these witnesses agreed very closely and fully corroborates the opinions stated above. It appears that the Reading train passed Pleasantville, three miles from the scene of the disaster, at a speed approaching 60 miles per hour. It was running probably not less than 50 miles per hour as it approached the distant signal. The point at which the engineer shut off steam and applied the brakes is uncertain, but it was probably not less than 900 ft. from the crossing and they may have been applied 100 to 200 ft back of the distant signal or 1,150 to 1,250 ft. from the crossing. The brakes appeared to have held well, as the brakeman on the train testified that he was thrown to the floor by the shock of their application, but the train was running at too high a speed to be stopped before it reached the crossing, and it struck the other train at a speed of 12 to 15 miles per hour.

It appears then that so far as the responsibility of employees are concerned, this terrible accident was due to an error of judgment of the engineer in approaching a distant signal at too high a speed, expecting, doubtless, to see the signals change to safety as he approached them. This is not the first time by any means in railway annals that disobedience to fixed signals has been the cause of serious accidents. We recall to mind among notable cases of this sort, a rear collision on the Fitchburg, near Boston, a few years ago; a drawbridge disaster near New Orleans at about the same time, and, as a still more notable cases the terrible disaster on the Grand Trunk Railway at the Richelieu River, in 1864, in which the number of killed and injured were greater than in almost any disaster in the history of railroading, and which was caused by the engineer running his train into the open draw in absolute disregard of a danger signal.

It may be said to be almost an axiom of railway practice that the two most dangerous points on a railway are a drawbridge opening, and a grade crossing of two railways. Many states have laws compelling trains to come to a full stop before crossing such points; but experience has shown that even this traffic-delaying expedient is far from being an infallible safeguard. On Nov. 21, 1862, a Boston & Maine train after stopping at the station at Charlestown, moved forward into an open draw at a rate hardly faster than a man could walk, and the accident caused the death of six persons. Not to enumerate other instances, it is sufficient to say that it is generally recognized to-day that the best protection for either grade crossings or drawbridges is an equipment of home and distant signals operated by an interlocking machine which also operates derailing switches, which are opened when the signals are at danger. In some states, notably in Illinois, where the law formerly required trains to come to a full stop when approaching a railway grade crossing, they are now allowed to proceed without stopping over crossings equipped with interlocking signals and derails.

The best practice in the protection of grade crossings and drawbridges now requires that either should have derailing switches interlocked with the signals, and in addition that electric locking should be applied to the machine to prevent the towerman from changing the position of the signals after he has given a clear track to a train until it has passed over the crossing.

Undoubtedly the greatest lesson for railway managers in this accident is that it is not safe to dispense with derailing switches at grade crossings. We are aware that some railway officers object that a derailment may cause as serious results as a collision. It is true that it may, but universal railroad experience shows that it very seldom does.

It is to be borne in mind always in considering this question that the moral effect of the derailing switch is such that it COMPELS obedience to the warning of the danger signals as no rules or discipline that the best manager can enforce can possibly do. The engineer knows that the normal position of the signals is at danger, and when he approaches them and sees them against him he too often thinks that it means nothing more than that the tower-operator has been a little dilatory in throwing his levers. But if he realize that to run past a danger signal means absolutely and invariably that his train is going off the rails, he has a much more powerful motive to induce him to keep his train under control as he approaches such signals.

The few advocates of automatic braking attachments to signals will doubtless use the Atlantic City collision as a warning text to prove the merit of their systems; but it is by no means clear that a safety device of this class would have prevented this accident. The engineer did apply his brakes, but he did not apply them soon enough. To have certainly prevented this accident an automatic brake-setting device would have to have been located probably at least 1,800 ft. from the crossing, and such an apparatus would be a serious hindrance to trains running at slow speeds.

When we take into account also the complications and difficulties which any automatic brake-setting attachment to signals must involve, it seems to be clear that the derailing switch is the best means yet devised for compelling obedience to a danger signal, and insuring also against a catastrophe in case of the sudden death or incapacity of the engineer, the failure of the brakes or other causes which may send a train past a danger signal without the engineer being blameable.

If any of our readers are still of the opinion that it is too dangerous to throw a train onto the ties, we can suggest nothing better than a trial of the German "sand track," described in one of our recent issues. It would be an inexpensive matter to add a few lengths of rail to the stub end of a derailing switch and cover it with sand, and experiments show that the retarding effects of such a track is greater than that offered to a train running over the ties.

Besides the necessity of the use of derailing switches, it seems to us that more care should be taken in defining the meaning and use of the distant signal in the instructions to engine men. There is a too prevalent idea, we fear, that the distant signal marks the point where brakes should be applied for a stop at the home signal, in case the semaphores are both against the train. Every railway manager should try to eradicate this idea from the minds of his men. The point where the brakes should be applied depends wholly on the speed of the train. Very slow trains have no need of or use for the distant signal, save in times of heavy fog or storm. It may be claimed that distant signals should be set back from the crossing far enough to enable the fastest train to be stopped by applying the brakes at the distant; but with some of the fast trains, running at speeds reaching 70 to 80 miles per hour, this would mean a great increase in the length of operating mechanism to the distant signal, additional trouble from temperature changes, etc., and greater difficulty on the part of the towerman in checking the movements of the distant signals. The better plan seems to be to keep distant signals where they now are (unless they are so located that they cannot be seen for some distance back) and give special instructions to engineers of fast trains respecting the speed at which distant signals may be passed.

It is a matter of history that the fall of the Ashtabula bridge in 1876, and ten years later the terrible disaster at White River, Vt., and at the fatal Bussey bridge had a great influence in bringing about a general inspection and overhauling of bridges and bridge floors, and the result was a great improvement in the railway bridges of this country. It is to be hoped that this fearful example of the dangers of grade crossings may cause greater care everywhere in their protection.

As we stated at the outset only five railway accidents in the United States have ever resulted in a greater number of deaths. The principal facts concerning the seven worst accidents ever recorded on railways of the United States are summarized in the following table:

Date.	Place and railroad.	Kind.	No. killed.
May 6, 1853	Norwalk, Ct. (N. Y. & N. H.)	Drawbridge,	46
July 17, 1856	Camphill, Pa. (Phil. & Reading)	Rear collision,	66
July 15, 1864	Port Jervis, N. Y. (Erie)	Head collision,	60
Dec. 29, 1876	Ashtabula, O. (L. S. & M. S.)	Bridge,	92
Aug. 10, 1887	Chatsworth, Ill. (T., P. & W'n.)	Culvert,	73
Oct. 10, 1888	Mud Run, Pa. (Lehigh Valley)	Rear collision,	60 to 70
July 30, 1896	Atlantic City, N. J. (Pa. & P. & R.)	Grade crossing,	46

THE RELATION BETWEEN PUTRID GASES AND typhoid fever, from the standpoint that such gases are predisposing causes of the disease, has been investigated by Dr. Giuseppe Alessi. By subjecting rats, guinea pigs and rabbits to an atmosphere containing the exhalations from excrementitious matter and later inoculating them with cultures of typhoid bacillus, watching the effects and making post mortem examinations of such animals as died, together with cultures from their organs, the doctor concludes that putrid gases predispose these animals to the pathogenic action of typhoid germs. Further and exhaustive studies led to the belief that the predisposition is caused by a combination of the gases given off by putrefaction, and not by any one of them, the animals being subjected to ammonia, sulphuretted hydrogen, carbonic acid, and other less well known gases, and subsequently inoculated with the typhoid bacillus. Long-continued breathing of the combined gases of putrefaction seemed to diminish the predisposition under discussion, but not to terminate it, although the experiments were limited in point of time. While discrediting the old theory which made the gases of putrefaction directly responsible for typhoid fever the experiments strongly confirm modern hygiene in its teachings that sewer air and other bad air should not be breathed. We are indebted to Mr. H. Alfred Roechling, Assoc. M. Inst. C. E., 14 Market St., Leicester, England, for a copy of Dr. Alessi's paper, reprinted, we suppose, for private circulation. The paper was translated by Misses E. and C. Harvey and contributed by Mr. Roechling to The Sanitary Institute, of which Mr. E. White Wallis, Parkes Museum, Margaret St., London, is secretary.

LETTERS TO THE EDITOR.

Summer Uniforms for Railway Employees.

Sir: American railway officers are as a rule noted for their practical good sense; but I have noticed of late what seems to me a great oversight on their part. During the hot weather of the present summer, when heat and humidity were competing to see which should do the most to make humanity suffer, and when everyone felt as if Adam's original costume were clothing enough, I have observed the conductors on several of our important railways sweltering and suffering in the heavy blue "Prince Alberts," which they are obliged to wear. It certainly ought to be possible to devise a uniform for summer wear, which would be far more comfortable, and I am sure that passenger trainmen and other railway employees would greatly appreciate the change. No man can perform his duties as well when bodily discomfort is constantly distracting his attention; and I believe that railway managers would find that uniforms for their employees suited to hot weather would pay large returns in the way of a better-looking and more polite staff, more alert in the performance of their duties. S .M. K.

New York, July 29, 1896.

Which Side of an Oak Tie to Lay Down.

Sir: Referring to the query of R. W. W. in your issue of July 23, as to which side of an oak tie should be up when laid in a dirt roadbed, one side having full face and the opposite side having corners rounded off, I think the rounded side should generally be placed up. Such a tie is frequently made from a tree large enough to make two ties to an 8 ft. section of the trunk, or what is commonly called a "split tie." If laid with the rounded side up, the grain of the wood will have a tendency to shed the water, whereas if laid with the full face, or heart side, up, the grain will tend to carry the water to the center of the tie. There would probably be at least ½-in. of sap at the rounded corners, and if placed down it will commence to rot quicker than if turned up; for in the latter position it will stand a better chance to dry out after rains. The full face side down will also hold better in the tamping. The rounded side will not give as good bearing for the rail, but in a dirt track it is fair to asume that the traffic is not heavy, consequently there will be no serious cutting of the rail into the tie. Yours very truly, F. G. Jonah.

Marine, Ill., July 27, 1896.

A Region Where Times are Good.

Sir: In this Bayou Lafourche section of Louisiana everything is on a boom. Good crops and plenty of money makes business good anywhere. A new railway is being built from the Mississippi River down the banks of Bayou Lafourche which will ultimately reach Lockport, a distance of about 60 miles. An ice factory has been started in Napoleonville and there is some talk of putting in water-works. Mr. Leon Godchaux, the largest sugar producer in the United States, is putting in an immense sugar mill and remodeling his Elm Hall refinery, enlarging its capacity from 900 tons per day to 1,200 tons. This is done to enable him to handle the enormous crop of 90,000 tons which he confidently expects to cut from this enormous estate. It is expected to turn out this season no less than 12,000,000 lbs. of fine quality "white granulated" sugar. The railway system on this plantation, consisting of 10 miles of track, will be extended about 4 miles, to enable him to handle the crop more expeditiously. Another 12-ton Baldwin locomotive will be added to the rolling stock. The track is of first-class steel rails with frogs and switches of the latest design.

A week ago the sugar house on the Souvenir Plantation, owned by Mr. Godchaux, was destroyed by fire. The loss amounted to $75,000. Within 12 hours after the fire started the plans were made and an order placed for a new refinery to take the place of the one burned. The contract calls for a complete sugar house, to be ready for grinding by Oct. 15 of this year. The new house will be of the latest design and double the capacity of the old one. W. Irving Willis.

Napoleonville, La., July 26, 1896.

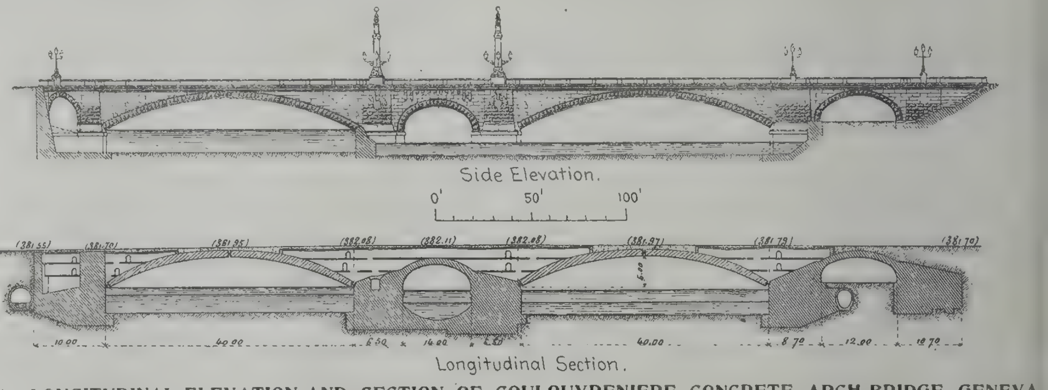


FIG. 1. - LONGITUDINAL ELEVATION AND SECTION OF COULOUVRENIERE CONCRETE ARCH BRIDGE, GENEVA, SWITZERLAND.

Bride's Sewer Flushing Device.

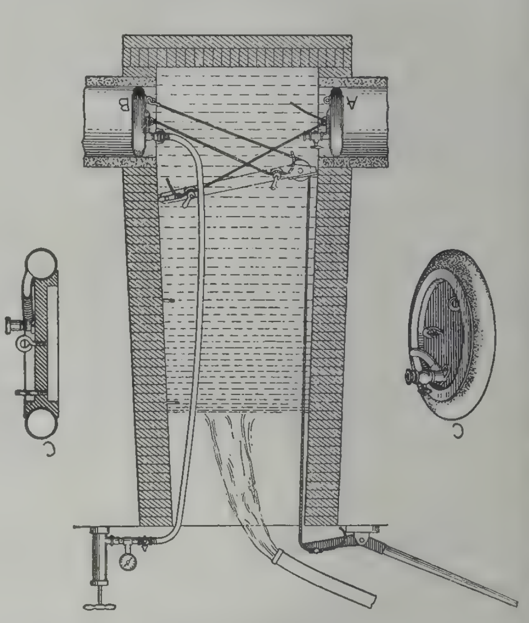
Sir: I enclose herewith a cut and description of a sewer flushing device which may be of interest to your readers. At the request of the inventor I gave it a trial on our sewers here and found it to work most satisfactorily.

In connection with the criticisms of flush tanks (see Eng. News, June 4, 1896), in the report of the annual convention of the American Water-Works Association, an inspection of this device is recommended.

Yours truly, Morris Hacker,
Civil Engineer Chevy Chase Land Co.

Chevy Chase, Md., June 22, 1896.

(The device in question is a stopper consisting of a circular block with a rubber ring around its rim. The ring is inflated after the stopper is inserted in the pipe, or pipes, leading from the manhole, thus making a water-tight seal. The manhole is then filled with water from a hose, or any other means provided, after which the stopper is suddenly withdrawn by means of the lever and accessories shown in the illustration. Mr. C. T. Bride, 129 B St., S. W., Washington, D. C., controls the device, which he states has been used by the sewer department of the District of Columbia.



A New Sewer Flushing Device.

It is, of course, no new thing to flush sewers by plugging the pipes leading from manholes. Where that system is in vogue this device may prove much more advantageous than some of those already in use, but automatic flush tanks will still be found advantageous and even necessary in many cities.—Ed.)

The Modified Darcy Formula and the New Westminster Steel Main Gagings.

Sir: So much attention is now being given to the very important practical question of how much water we may expect a pipe of given material, diameter and hydraulic gradient, and laid under ordinary practical conditions, to deliver, that such a communication as that contained in your issue of July 30, under the title of "Flowage Test of a 14-in. Riveted Steel Pipe," cannot fail to be interesting.

In this test the data were as follows: Observed discharge, 0.99 cu. ft. per sec.; fall per 1,000, 0.455; diameter, 1,167 ft.; character of pipe, riveted steel, rivets not countersunk. Applying the modification of Darcy's well-known formula for rough cast-iron pipes already communicated to your paper upon a previous occasion, we find an exact correspondence with observed results.

In order that your readers may check this assertion, if they see fit, I will give the generalized formula of Darcy, as follows:

$$Q = \sqrt{D^5 . h},$$

in which Q = cu. ft. per sec.; D = diameter in feet, and h = fall per thousand.

Inserting the given factors:

$$Q = \sqrt{1.167^5 \times 0.455} = 0.99 \text{ cu ft},$$

as observed,

From this it would appear that a new riveted steel pipe of the character described in the report is under the same conditions as regards discharge as a rough cast-iron one. After some years of service the above pipe will no doubt give a reduced delivery.

I have already taken occasion to call attention to the great simplicity and practical utility of the above generalized formula. It is adapted to the case of very rough cast-iron pipes, and will therefore in many cases give too small a discharge; in other words, it contains a factor of safety, as all practical engineering formulas should do. By a curious cancelling of factors, if we make Q = U. S. gallons per minute, and D = diameter in inches, then the above formula gives a discharge about 10% greater than for feet and seconds, and in many cases this would be nearer the truth than the original formula.

Notes and Queries.

A. O. G. asks where iron sidewalks are manufactured and what are their merits and faults?

◆

THE COULOUVRENIERE CONCRETE ARCH BRIDGE, GENEVA, SWITZERLAND.

The success with which concrete, with or without a metal skeleton, lends itself to aesthetic treatment in the construction of street and park bridges has been mentioned often in Engineering News, and from time to time prominent American structures of this type have been described and illustrated in its columns. In Europe, however, the use of concrete for roadway bridges has been more extensive than in this country, and it was in Germany that the well-known concrete and iron constructions of Monier and Melan were first developed and exploited. But, besides these combination structures, concrete arches without metal skeletons have been built to a considerable extent in Europe, and European engineers are not infrequently found who prefer them to any of the patented constructions. As an example of this non-skeleton construction we illustrate herewith the Coulouvreniere Bridge, a concrete bridge of two 131.2-ft. spans, recently completed at Geneva, Switzerland. Besides its handsome appearance this bridge is notable for the boldness of its design, considering the material used and for numerous structural details which are not exemplified by such concrete arches as have been constructed in America up to the present time.

The Coulouvreniere Bridge crosses the River Rhone at Geneva, Switzerland, and was constructed to replace a bridge built in 1857, which in aesthetic qualities and strength had become undesirable. It was decided that the new bridge should be of concrete and should consist of two main arches separated by a central pier of considerable width, but the details of its construction and design were opened to competition. Designs were presented both for combination concrete and iron constructions and for articulated concrete construction, and the latter construction was adopted as preferable by the experts, who were Prof. Ritter, of the Zurich Polytechnic School, and Mr. Elstres, Engineer of the Jura-Simplon Ry. Co. The chief reason given by the experts for their choice was the lack of empirical evidence supporting the various theories as to the exact action of combination iron and concrete arches under stress; it was considered doubtful if the extension of the metal tension members under stress would not rupture the concrete in which they were imbedded, considering the length of the span.

The arch construction adopted can be hardly better described than by the term articulated, there being a steel joint at each springing line and at the crown, designed to fix definitely the curve of pressure and to reduce the danger of fissures from expansion or settlement under load. This design was submitted by M. Bois, one of the competitors, and has a counterpart in the Munderkingen Bridge in Wurtemberg. Fig. 1 shows a side elevation and longitudinal section of the structure. The span of each of the large arches is 40 m. (131.2 ft.) and the rise is 5.55 m. (18.2 ft.). The total length of the bridge is 152 m. (498.56 ft.), the width of roadway 11 m. (36 ft.), the width of sidewalks 3.5 m. (11.48 ft.) each, and the width over all 20 m. (65.6 ft.). The left-hand arch crosses the main channel of the river which always flows full since it is separated from the other branch of the river by a wing dam, but in high water both channels flow full. The center and right-hand arches cross this right-hand channel, in which the flow varies from almost nothing to 2,000 c. m. per second. The 12 m. (39.36 ft.) arch at the extreme right spans the quay on the right bank of the river.

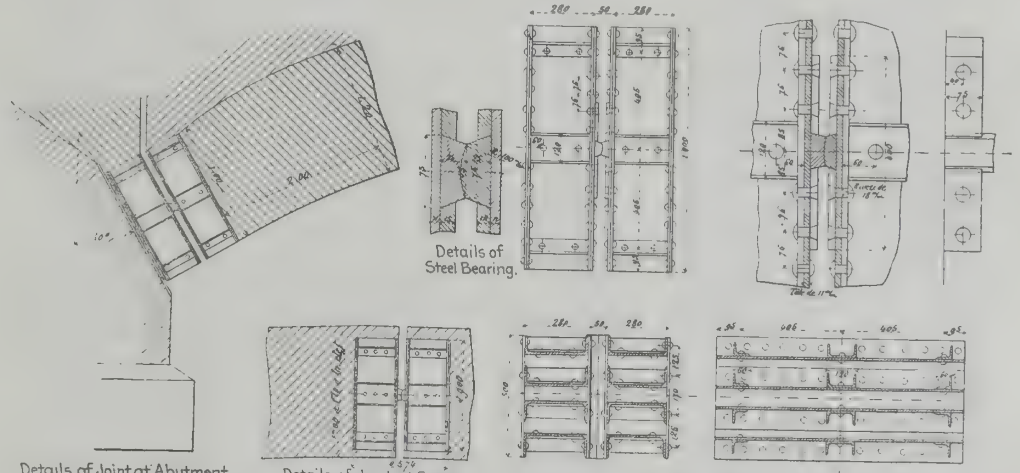
With the exception of the left abutment, no great difficulties were encountered in any of the foundation work. This left abutment was on a bed of mud, and to render it safe against the weight a large number of piles had to be driven and capped with a thick mass of concrete. Fig. 2 shows the foundation as built and other features which will be noted further on. The character of the superstructure, of course, required unusual care to secure an unyielding foundation.

As has already been stated the main arches had spans of 40 m. (131.2 ft.) with three hinges or articulations each. Fig. 3 shows the character of the articulations and details of the abutment hinge. The crown hinge was exactly the same, but only 0.9 m. (2.95 ft.) deep. They were constructed entirely of steel and entirely buried in the concrete, except, of course, the bearing faces as shown. Each articulation or joint, running clear across the arch, required 60 frames of the character shown, or 30 concave and 30 convex bearings. Fig. 2 shows how each articulation is continued up through the spandrel filling.

To construct the arches centers were first built, as shown by Fig. 2. Upon these the concrete was laid in transverse, voussoir-like layers, Fig. 4, showing the method of work. Each voussoir was 1 m. (3.28 ft.) thick along the line of the intrados. Except that care was taken to even up the load on the centers by having voussoirs on the opposite haunches under construction simultaneously and to keep the centers carefully leveled, no exceptional precautions were taken. The composition of the concrete was 425 kg. (935 lbs.) of cement per 1 cu.m. (1.308 cu.yd.) of aggregate, which consisted of pebbles crushed to pass a hole of 3 cm. (1.18 in.) diameter. The concrete was mixed by machine. The placing of the concrete for the right-hand arch took 20 days and for the left-hand arch 10 days. The center for both arches was struck about 2½ months after their completion, the lowering being done gradually by letting the sand out of the boxes in which the posts rested. The settlement of the arches were as follows:

	Right Arch.	Left Arch.
Settlement upon striking center..	22 mm. (0.86 in.)	30 mm. (1.18 ins.)
Total settlement.	42 mm.(1.65 ins.)	38 mm. (1.49 ins.)

The character of the spandrel filling is shown clearly by Fig. 2, as is also the construction of the roadway and sidewalks. The sidewalk covers are plates of concrete with an embedded meshwork of iron. Various dimensions and details of construction not mentioned are shown by the illustrations. Exteriorly the bridge has the appearance of a stone structure of different kinds of stone, the piers being a yellow stone resting on granite, the spandrel walls white, the arch ring the natural concrete color, the cornice blue marble and the balustrade rose-colored granite. The construction was done by the city of Geneva, under the direction of its engineer, M. Butticaz.



Details of Steel Bearing.
Details of Joint at Abutment.
Details of Joint at Crown.
Details of Hinges at Springing Line.

FIG. 3.—DETAILS OF ARCH HINGES, COULOUVRENIERE BRIDGE.

In its arch construction this bridge is a counterpart of the Munderkingen Bridge in Wurtemberg, which has a span of 50 m. (164 ft.) and a rise of 5 m. (16.4 ft.). Since the completion of the Coulouvreniere Bridge it has been subjected to some unusually heavy loads without exhibiting any deflection. The most notable of these loads were two locomotives weighing, together, 150 tons, which were taken across the structure one behind the other, and a test load of 500 kg. (1,100 lbs.) of gravel per square meter.

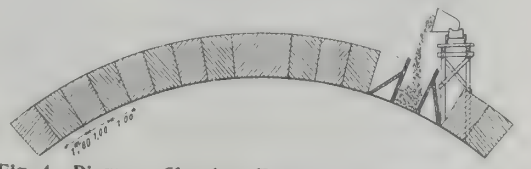


Fig. 4.—Diagram Showing Manner of Constructing Concrete Arch Ring, Coulouvreniere Bridge.

For the matter from which this description has been prepared we are indebted to our French contemporary, "Le Genie Civil."

PRELIMINARY REPORT OF THE COMMITTEE ON TESTS OF FIREPROOFING.

As most of our readers will remember, a series of tests of the resistance of structural materials to fire was arranged for several months ago, and the work was placed in the charge of an able committee consisting of Messrs. S. Albert Reed, representing the Tariff Association of New York; Geo. L. Heins, representing the Architectural League of New York, and Messrs. H. De B. Parsons and Thos. F. Rowland, Jr., representing the American Society of Mechanical Engineers.

This committee has just presented a preliminary report, showing the progress made to date in their work. The following is their report substantially in full:

Your committee, after having effected its own organization, determined to add to its numbers by the creation of an Advisory Board. This step was taken for the purpose of more widely increasing the interest taken in the experiments, and also to prevent, as far as possible, the impression that the work was of a sectional or local character. The names of the gentlemen who accepted invitations to serve on this Advisory Board, are as follows:

Edward Atkinson, President Boston Manufacturers' Mutual Fire Ins. Co.; Osborne Howes, Secretary Boston Board of Fire Underwriters; Charles A. Hexamer, Secretary Philadelphia Fire Underwriters' Association; H. H. Glidden, Manager Chicago Fire Underwriters' Association; W. Martin Aiken, Supervising Architect, U. S. Treasury Department, and Representative, Illinois Chapter, American Inst. of Architects; Stevenson Constable, Superintendent of Building Department, New York city; Geo. B. Post, New York Chapter, American Inst. of Architects; F. H. Kindl, Structural Engineer, Carnegie Steel Co.; John R. Freeman, Chief of Inspection Department Factory Mutual Ins. Co's; Henry Morton, President Stevens Institute of Technology; C. J. H. Woodbury, M. Am. Soc. C. E.: H. B. Dwight, Dwight Survey & Protection Bureau, New York; F. C. Moore, Delegate N. Y. Board of Fire Underwriters to Board of Examiners of Department of Buildings; Wm. A. Wahl, Secretary Franklin Institute, Philadelphia; John T. Williams.

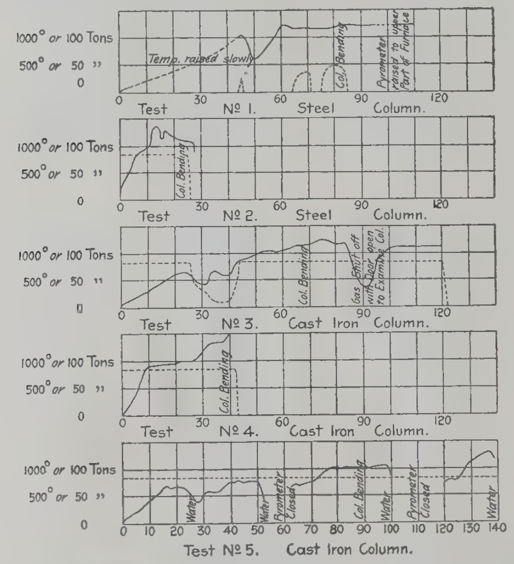

Fig. 2.--Results of Tests of Loaded Columns Exposed to Heat.

(Solid lines show temperature. Dotted lines show load on column.)

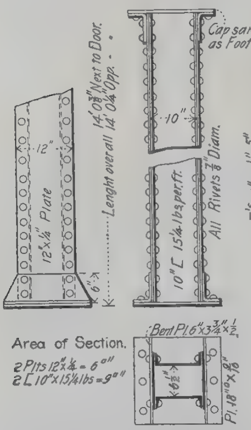

Fig. 3.—Details of Steel Column Tested in Test No. 1.

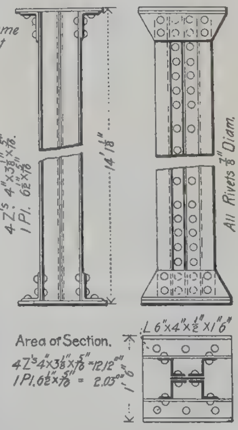

Fig. 4.—Details of Steel Column Tested in Test No. 2.

During the winter just past your committee erected a testing plant, as shown in the accompanying photograph (Fig. 1). The gas producer in the back ground is 9 ft. in diameter by 12 ft. in height, and is equipped with a hopper valve on top. Gas is generated by means of steam from the boiler as shown, and carried into the furnaces through pipes, as clearly indicated in Fig. 1. The foundation shown on the left is ready for the erection upon it of a furnace for testing beams and floors. It will be 27 ft. × 12 ft., but it can be arranged to take larger beams if so desired. The furnace shown on the right is for testing columns and is 14 ft. square, outside measurement.

The arched roof is made of fire brick and is independent of the side walls, being supported by outside corner posts. The walls are of common brick, but can easily be changed so that experiments can be made on other materials. One side wall and the end wall with the door, are 12½ ins. in thickness; the rear wall is 8½ ins. and the fourth wall is 4 ins. inside, 2 ins. air space and 8½ ins. outside, making a total thickness of 14½ ins. The floor is covered with fire brick, with openings left for the branch gas pipes and air spaces to support the combustion. These branch gas pipes are 4 ins. in diameter, capped with tuyeres reduced to 2 ins. In order to increase the temperature when desired, a barrel of naphtha is connected by means of a small pipe and blown into the gas pipe at the "Y" branch, by means of a steam jet.

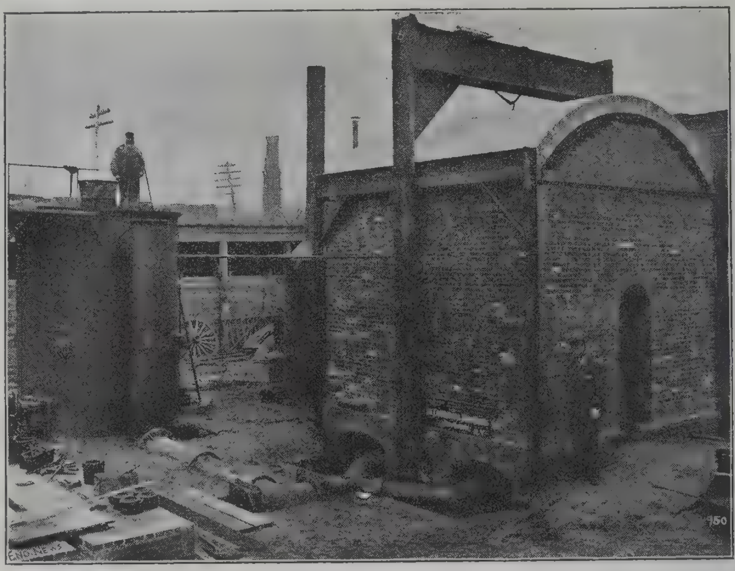

FIG. 1.—APPARATUS FOR TESTING THE EFFECT OF HEAT UPON STRUCTURAL MATERIALS.

The column is placed in compression by means of an hydraulic ram underneath, resting on three 24-in. I-beams, the same as those across the top of the furnace shown in the photograph. In order to keep the entire length of the column within the furnace, filler blocks of cast iron are placed between the ends of the column and these I-beams. The hydraulic ram is 12 ins. in diameter, and the water pressure can be carried to 2,500 lbs. per sq. in. The temperature is measured by means of a Uchling & Steinbart pyrometer (illustrated and described in Engineering News, Nov. 14, 1895).

The money to carry out this work has been advanced by various parties, and, together with the committee's disbursements, is shown in the accompanying treasurer's report.

(We omit the detailed report. It shows that $3,055 have been subscribed, chiefly by underwriters' associations, and $2,336.38 have been expended, of which about $2,000 was for constructing the apparatus shown in Fig. 1. The committee still owes $766.92, thus having spent to date about $30 more than the amount subscribed.—Ed.)

Your committee decided that it would be best to make the tests according to the following programme:

1. That a series of tests be made on columns of steel and of cast iron, without any fire protection whatever, these tests then to be taken as a basis of comparison with those that follow.

3. That a series of tests be made on unprotected beams and cast-iron columns, protected with different materials and in different ways.

3. That a series of tests be made on unprotected beams and girders.

4. That a series of tests be made on protected beams and girders.

It has also been proposed that each series be divided for test both with and without water.

Your committee has communicated with many manufacturers of fireproofing materials and has been informed that these manufacturers will submit their materials for purposes of tests.

Results of Tests of Unprotected Columns.

The result of this series of tests is shown in the accompanying diagram, Fig. 2, where the solid lines represent the temperature and the dotted lines the loads on the columns.

Test No. 1 was made on a steel column and the temperature was raised rapidly. Test No. 3 was made on a cast-iron column under similar conditions. Both columns began to fail as soon as they showed "red."

Test No. 2 was made on a steel column and the temperature was raised more slowly than in the other tests just described. Test No. 4 was made on a cast-iron column under similar conditions. Both these columns failed when they began to show "red," although the time was longer than in Tests Nos. 1 and 3.

Test No. 5 was made on a cast-iron column, and after heating a jet of water was thrown upon it through a ¾-in. nozzle. The column was first heated to 675° and then quenched with water without injury. The heat was then slowly raised again to 775° and the column again quenched with water. The heat was then raised slowly to a temperature of 1,075°, and the column, which then showed a "dull redness," was again quenched with water. The heat was then raised again to 1,300°, and the column, which now showed a "bright red," was again quenched with water. The column was beginning to yield by bending just before the last application of the water. The column was apparently unaffected by water, although it failed by bending under the load, the same as in Tests 3 and 4.

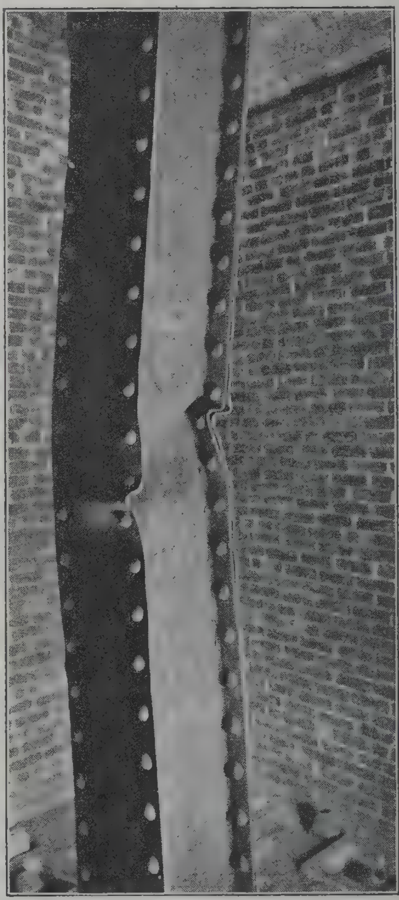

Fig. 5.—View of Column (Test No. 1) in the Furnace After Testing.

Detailed Log of Tests.

Column Test No. 1.—Fire Test without Water, Steel Column, May 19, 1896.

The walls of the furnace were of common brick, as already described, and the door was closed with a double thickness of sheet iron, which made the opening practically tight. The column was a Carnegie steel box channel, of the dimensions shown in Fig. 3 and was unprotected.

The gas producer was fired the day before, with valve closed against the furnace. The packing in the hydraulic cylinder leaked and a fitting of the pipe gave out as the test started. These causes delayed the use of the water pressure.

Log.

Time, h. m.	Pyrometer deg. F.	Hyd. pressure, tot'l l'd, tons.	Remarks.
10:35	.....	.....	Wood fire lit.
10:45	.....	.....	Gas turned into furnace.
11:02	.....	.....	Furnace door closed.
11:03	.....	.....	Naphtha valve slightly open.
11:13	.....	.....	Pyrometer put in furnace through lower hole, 2½ ft. abv. furnace door, with point 12 ins. from column.
11:19	1,025	.....	Pressure on column; light load.
11:20	1,050	.....	Pyrometer point 24 ins. from column.
11:25	600	.....	Raking gas producer; gas shut.
11:28	.....	.....	Gas turned on again.
11:33	1,025	.....	No naphtha.
11:36	1,225	.....	Half faucet of naphtha.
11:38	1,200	.....	
11:40	1,175	14.13	Water pressure on.
11:41	1,180	28.26	Quarter faucet of naphtha.
11:46	1,175	.....	Pressure off, water valve rep'k'd.
11:50	1,175	.....	Closed all air openings; water pressure on.
11:55	1,200	48.06	Column began to show "red."
11:56	1,210	.....	Column began to yield.
11:59	1,225	42.41	Hydraulic pressure falling fast.
12:10	1,230	.....	Pyrometer shut off; raised to upper hole, 8½ ft. above floor, and point 3 ft. from column.
12:16	1,230	.....	
12:25	1,250	.....	Gas shut off.

The column would have failed sooner if the working load of 80 tons could have been used. The result of the test is shown in the flashlight photograph (Fig. 5) taken of the column before it was disturbed. After the column was removed from the furnace Fig. 6 was taken. The brick walls of the furnace were cracked, the greatest damage taking place where one wall was bonded into the next and the cracks at these places extended through the bricks. Along the horizontal joints the walls cracked most on the bond courses. All the walls were hot, the 8-in. wall being too hot to hold the hand in contact with it.

Strength by Gordon's formula:

Breaking strength, per sq. in......45,630 lbs.
Area of cross-section ....15 sq. ins.
Breaking load......15 × 45,630 = 684,450 lbs. = 342 tons.

Actual greatest load, cold, 141.4 tons, with no change of form.

Column Test No. 2.—Fire Test without Water; Steel Column; Furnace Same as Test No. 1. May 27, 1896.

The column was a Carnegie steel Z-bar, as shown in Fig. 4, and was uncovered.

Log.

Time, h. m.	Pyrometer deg. F.	Hyd. pressure, tot'l l'd, tons.	Remarks.
2:23	80	.....	Pyrometer point 3 ft. from col.
2:24	200	84.8	Wood fire lit.
2:30	650	84.8	Gas turned on.
2:33	....	84.8	Door closed; full cock naphtha.
2:35	1,000	84.8	One-quarter cock of naphtha.
2:36	1,300	84.8	
2:37	1,350	84.8	
2:38	1,375	84.8	Naphtha closed.
2:39	1,300	84.8	
2:40	1,125	84.8	One-eighth cock of naphtha.
2:40½	1,300	84.8	
2:41	1,325	84.8	
2:42	1,250	84.8	
2:43	1,200	84.8	
2:44	1,175	84.8	Naph. cock closed to "dropping"
2:45	.....	84.8	Pyrometer moved to 2 ft. from column as flame touched point.
2:46	1,125	84.8	Column began to yield.
2:47	1,125	84.8	Column yielding fast.
2:49	1,100	84.8	Impossible maintain hyd. press.
2:51	1,100	84.8	Pump and gas stopped.
2:52	900	84.8	Pyrometer closed.

The result of this test is shown in the photograph, Fig. 7.

Strength by Gordon's formula:

Breaking strength, per sq. in......42,820 lbs.
Area of cross-section ....14.15 sq. ins.
Breaking load..14.15 × 42,820 = 605,900 lbs. = 303 tons.

Column Test No. 3.—Fire Test without Water; Cast-iron Column; Furnace same as Tests 1 and 2. June 30, '96.

The column was a cast iron, hollow, round column, with flanges faced on both ends, as shown in Fig. 8, and was uncovered. It was cast horizontally, with a dry sand core, by the Cornell Iron Works, New York.

FIGS. 6 TO 10.—VIEWS OF COLUMNS AFTER REMOVAL FROM THE FURNACE.

Strength by Gordon's formula was as follows:

Breaking strength ....902,000 lbs.
Safe load..... ....1-5 × 902,000 = 180,400 lbs. = 90.2 tons.

The result of test No. 3 is shown in the photograph, Fig. 8.

Column Test No. 4.—Fire Test without Water; Cast-iron Column; Furnace same as Tests 1, 2, and 3. July 6, 1896.

The column was a cast-iron, hollow, round column with flanges faced on both ends, and was uncovered. It was cast horizontally with a dry sand core, by the Cornell Iron Works, N. Y. The column had a length over all of 13 ft. ¼-in., thickness of flanges 1⅝ ins. flanges reinforced by four ribs, each ⅞-in. thick, reaching from outer end of flange to cylinder at an angle of about 45°.

3:03	1,500	84.8	
3:03½	1,525	84.8	Column yielding fast.
3:05	1,550	84.8	Column broke suddenly.

The result of the test is shown in the photograph, Fig. 9. The fracture occurred at about the center of the column where the deflection was the greatest. There was a crack about 5 ins. long, about 7 ins. above the fracture on the convex side of the column, showing that the column first pulled apart on the outside of the bend. No water was thrown on this column during the test.

Column Test No. 5.—Fire Test with Water; Cast-iron Column; Furnace same as Tests 1, 2, 3 and 4. July 10, 1896.

The column was a cast-iron, hollow, round column, with flanges faced on both ends, and was uncovered. It was cast horizontally with a dry sand core, by the Cornell

Iron Works, N. Y. The column was 8 ins. in diameter, outside and 1 in. thick, the end flanges were 1⅝ ins. thick, and were reinforced with four ribs, as in test No. 4. There was a slight defect in this casting, there being a porous portion a few inches long on one side about 3 ft. 6 ins. from the lower end.

Water was thrown upon the column through about 50 ft. of 2½-in rubber hose, and a ¾-in. nozzle. The pressure at the hydrant was 50 lbs.

THE BRIDGE BRAKE.

By Robert Grimshaw.

The deflection of bridges or similar structures depends, other things being equal, upon their span. But the increase of deflection and change of form due to a moving load becomes less important, in a statical sense, as the proportion of live to dead load diminishes with increase of span. It is, however, far otherwise when we consider the oscillations caused by a moving load having impulses with a regular period, as for instance those due to marching troops or trotting horses; as such oscillations, when their rate harmonizes with that of the structure, increase successively in amplitude.

It has been demonstrated* that the period of vertical oscillations of a prismatic girder may be calculated from the deflections arising not only from its nearly-uniformly distributed dead and live loads, but from isolated loads. This is also the case with lateral vibrations, except that with these those deflections (other than those caused by wind and so-called centrifugal force) must be calculated on the supposition that the load acts in the same direction as the impulse. For example: With a cylindrical girder having the same moment of inertia in every direction transverse to its length, the vibration-period is the same in every direction, no matter what the direction of the impulses; as only the masses and their elasticity come into play, gravity being of influence only as regards the intensity of the impulses.

Besides the so-called centrifugal force, wind may cause lateral as well as vertical undulations—which in the case of the chains of Telford's Menai suspension bridge, increased so greatly that part of the carriageway got loose and hung down like an apron, to the water, 100 ft. below. To prevent a repetition of this occurrence, the two chains, one above the other, on each side of the bridge, were connected by lattice-work.

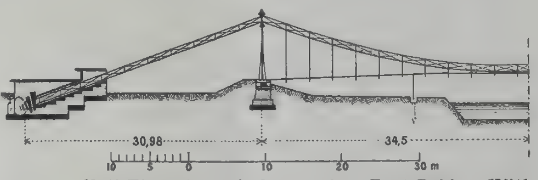

Fig. 1.—Half-Elevation of Suspension Foot-Bridge With Attachments for Preventing Oscillations.

The same manner of stiffening was applied on a railway bridge over the Danube Canal at Vienna, by Schnirch; but although it had served the desired purpose at the Menai bridge, it did not in the Vienna structure, which carried a railway track, and it was in consequence afterwards removed.

While short beams have such short vibration periods that impulsive moving loads can cause them no harm by successively-increasing vibration amplitude, girders of every kind, beyond a certain length, may be exposed (no matter how stiff they may be) to injurious vibrations by such influences as a body of marching men, keeping step; trotting horses, a locomotive having excessive counterbalance weights, etc.

The oscillation-period, in seconds, of a prismatic beam is stated by Koepcke (in the second paper quoted in the footnote) to be dependent on the deflection u_1 caused by a single load in the centre, and that u_2, caused by an equally-distributed load, and is equal to

$$t = \sqrt{0.0040252\ u_1 + 0.0031736\ u_2};$$

u_1 and u_2 being expressed in millimeters.

With an unloaded girder, only the deflection u_2, caused by the distributed dead load, comes into play; therefore the limit of resistance against vertical vibrations caused by a body of men keeping step at the rate of three paces per second, will be

$$u_2 = \frac{t^2}{0.003176} = \frac{0.3333^2}{0.003176} = 35 \text{ mm.}$$

say 1.38 ins., and if they march at only two paces per second, the deflection will be

$$u_2 = \frac{0.5^2}{0.003176} = 78.7 \text{ mm.,}$$

or say 3.1 ins.

Supposing the coefficient of elasticity of a prismatic girder to be 2,000,000 kilos. per sq. cm. (= say 28,446,000 lbs. per sq. in.); the ratio of height to span $\frac{h}{l} = \frac{1}{10}$, and the greatest stress in the center 800 kilos. per sq. cm. (=say 11,378 lbs. per sq. in.); the expression for the extension and compression of the fibers

$$\delta = \frac{24 \times u_2 h}{5\ l^2} = \frac{24 u_2}{50\ l} = \frac{800}{2,000,000} =$$

0.0004; and as for men at a quickstep, u_2 is 35 mm. = 1.38 ins., we have the span l, corresponding to this step, as

$$l = \frac{24 \times 35 \text{ mm.}}{5 \times 0.0004 \times 10 \times 1000} = 42 \text{ meters,}$$

or say 137.8 ft.

For men marching at two paces per second, the deflection of a beam undulating in half-second periods being 78.7 mm. = 3.1 ins., we have the minimum span of such a beam

$$l = \frac{24 \times 78.7}{5 \times 0.0004 \times 10 \times 1000} = 94.4 \text{ meters,}$$

or say 309.7 ft.*

As these quantities, 42 and 94.4 meters, or 137.8 and 309.7 ft. respectively, are small, the vibrations of common iron girders would occur oftener if the passive resistances of sliding or of rolling friction on the piers did not consume the "vis viva" of marching men, etc. This sliding or rolling is due to the lengthening of the lower flange of the girder under tension, which necessitates that one end or both shall slide on the bed-plates. In many cases such frictional resistance is sufficient to prevent increasing deflection under repeated impulses, regular in time and amount, such as those due to marching troops.

The absence of such friction on the bed-plates causes girders in the form of double arches symmetrical to a horizontal axis, such as those over the Rhine at Mayence (by Pauli), over the Elbe at Hamburg (by Lenz), or the Tamar at Saltash (by Brunel) to be more subject than straight girders to vertical vibrations.

As the vibration-period, and the danger, decreased with the diminution of the real or possible deflections by dead and live loads, so continuous girders are less subject to vibrations than are those covering only one span, or which, like those of the Gerbex type, are sectional; and still less so than all arch and suspension bridges.

The counteracting of the creation of oscillations or the shortening of their periods, may be effected.

(1) By strengthening the structure; or

(2) By the addition of special parts, acting like the finger of a violin-player in generating overtones; or

(3) By frictional devices.

The following examples are cited by Koepcke:

(1) The suspension foot-bridge shown in Fig. 1 was liable to strong oscillations by the passage of even a few men keeping step. This was stopped by a contrivance which was used in some other and similar instances for a similar reason; a friction brake.*

Although the chains of each pair on each side were bound together by lattice-work, this stiffening was not sufficient, as the span was 69 meters = 226.4 ft.; and the more so as the links of the chain had a cross-section of but 100 × 8 mm. = 3.937 × 0.315 ins., and as the wooden floor was light. The chain was easily deformed by unsymmetrical loads; and as the bridge had a width of only 2.3 meters = 7.55 ft., it rocked like a boat by reason of the deformations of the two sides being different.

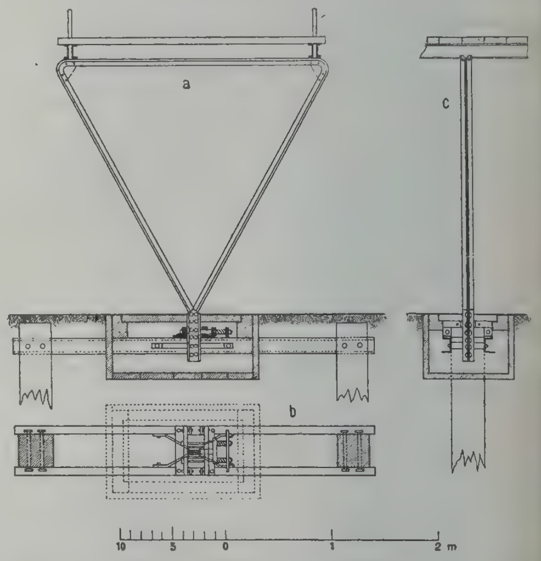

Fig. 2.—Details of "Brake" for Suspension Foot Bridge

In this case there were attached to the bridge, at the center and at a point 15 m. (49.2 ft.) therefrom, two devices shown in Fig. 2; each consisting of a triangular frame fastened under the footway, and having at its lower end a vertical continuation sliding in a clamp, which latter was placed below on the river-bank and acted on by springs, the tension of which was regulated by screws. The springs caused a frictional resistance of about 500 kilos. = 1,100 lbs., which was sufficient to resist the oscillations caused by troops passing over the bridge. The frames help, by their stiffness, to prevent rocking, and to keep the brake-poles vertical and their upper frames horizontal.

---

*Koepcke: "Deutsche Bauzeitung," pp. 163 of 1885 and 549 of 1886.

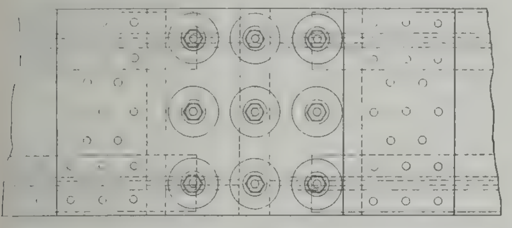
*When we notice that the deflection for 3 steps and 2 steps per second are 1.38 and 3.1 ins. respectively, and the spans corresponding to those rates of undulation are practically 138 and 310 ft. respectively, we have a ready rule (which I believe I am the first to point out) for getting the span from the deflection; the span in feet is 100 times the deflection in inches; and the span in meters is 12 times the deflection in centimeters.

*See "Deutsche Bauzeitung," as before cited.

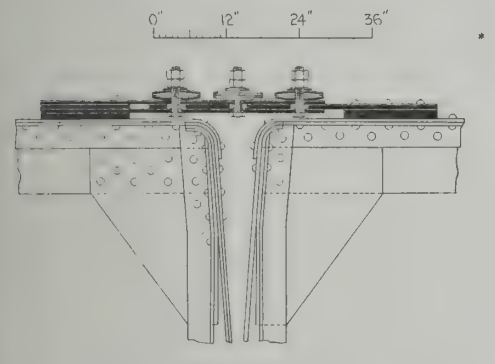
The supports on brakes may readily be raised in case of high water to prevent damage by floating ice, or drift—and as their resistance is but slight (say 500 kilos. = 1,100 lbs. each) the stresses in the main members of the bridge, and the motions due to temperature-changes and load-variations, are not materially affected.

This device proved efficient, and is still in place and effective.

In the case of the famous Loschwitz-Blasewitz rigid-suspension bridge over the Elbe, above Dresden, there are applied brakes at the center, to join the ends of the stiffening-girders. As the suspension girders require free movement about the hinges at the water, only a yielding connection, operating by friction, is here admissible. This connection is simply but perfectly effected by clamping an iron plate 20 mm. (0.787 in.) thick between two others, each 15 mm. (0.59 in.) thick, the compression being effected by nine screws each 35 mm. (1.15 in.) in diameter, held in constant tension by a pair of Belleville-steel spring washers. (See Fig. 3.) The clamped plate has slots cut lengthwise in it, long enough to permit the greatest changes of position caused by extremes of temperature and of load. The stresses in the screws being calculated at about 1,000 kilos. per sq. cm. (14,223 lbs. per sq. in.), and the coefficient of friction being 0.2, this would show a resistance of



Plan.



Longitudinal Section.

Fig. 3.—Plan and Sectional Elevation of "Brake" at Junction of Stiffening Girders of the Loschwitz-Blasewitz Suspension Bridge. Dresden.

$$\frac{2 \times 3.5^2 \times 3.14 \times 9 \times 1000 \times 0.2}{4} = 34,650$$

kilos., or say 76,403 lbs. As this resistance is applied at a point 2½ meters above the hinge, the moment of resistance is 2.5 × 34650 = 86.6 ton-meters, or say 281 English foot-tons on either side of the bridge; representing a very considerable capacity of resistance against oscillation from marching men, trotting horses, etc.

The sliding friction of about 35 meters = 34.45 long English tons, being but slight in comparison with the stresses on the hinges, which range between 579 and 826 metric tons (= say 570 and 814 gross tons); and being slight even compared with the strength of the compression-member of the stiffening-girder, which member has a cross-section of 1.5 × 87 × 4 ×10 ×1 = 210 sq. cm. = 32.55 sq. ins., it is therefore not harmful.

A similar contrivance has been applied in this same bridge to the studs of the tension-members of the side-girders, which move in holes in the pillars. Each stud being clamped by two screws, the sliding friction is, under the same assumption as before,

$$\frac{2 \times 2 \times 3.5^2 \times 3.14 \times 1000 \times 0.2}{4} = 7,693$$

kilos., or say 16,955 lbs.

Here the distance from the fulcrum or pillar-head being 25 meters = 82 ft., the moment of resistance is 25 × 7.693 = 192.3 ton-meters = say 362 foot-tons.

The bridge brake is applicable to almost every other form of bridge construction. In rope and chain suspension-bridges of the ordinary type, the oblique stays between the points of suspension and the roadway frames should not be bolted or riveted to the latter, but fastened by stirrups. In some cases the above-described method adopted at the Loschwitz bridge, will be feasible; either vertical or inclined supports being used.

Bracing such as that of the Lambeth bridge over the Thames at London, which acts by friction, as for instance in the center and at the pillars, will prevent or lessen oscillation without perceptibly affecting the necessary movability.

The bridge brake is also applicable to girder bridges. The ends of girders on the pillars may be connected by the same contrivance as is used at Loschwitz, in the center.

The device is especially suitable to cantilever girders, for making the connections between sections, and thus preventing both horizontal and vertical undulations.

STREET RAILWAY STATISTICS OF THE UNITED STATES.

We are indebted to our contemporary, "The Street Railway Journal," for the accompanying table showing the mileage, rolling stock and capitalization of the street railways of the United States. The figures in the table were compiled from returns from the various street railway companies collected by our contemporary for its financial supplement: "American Street Railway Investments," which was reviewed in our issue of July 30.

The caution is given that the above figures are to some extent approximate, there being a certain percentage of companies which refuse to give information. Our contemporary estimates that figures for capital stock and funded debt are in error not more than 7% in any state, and in most of the states not more than 3 or 4%. Its statistics for mileage and cars do not differ from the correct figures more than 3 or 4% in any one state. While these statistics are published in the August number of our contemporary, it will be understood, of course, that the time necessary to collect and compile returns is such that the statistics actually represent the conditions of some months ago. Probably it would be not far from right to say that they represent the condition of street railway properties at the beginning of 1896.

It will be seen that about six-sevenths of the total mileage is equipped with electric traction. About 1,200 miles of horse-car roads and 600 miles each of dummy and cable roads make up the balance. The enormous capitalization of the roads in the Middle States, averaging $147,300 per mile, suggests the idea that capitalization is based on earning power rather than on the actual cost of the roads.

NOTES FROM THE ENGINEERING SCHOOLS.

The catalogue of Purdue University at Lafayette, Ind., shows a total of 635 students in attendance during the year just closed. The class just graduated numbered 108. The University's famous locomotive testing plant has made it widely known in railway circles, and if the Master Mechanics' Association had its scholarship endowment fund to dispose of over again there is no doubt that Purdue would be the institution selected.

The commencement announcement of La Fayette College, Easton, Pa., shows a graduating class numbering 50 members, of whom 20 received degrees in technical courses; 8 as civil engineers, 2 as mining engineers, 6 as electrical engineers and 4 received the degree of B. S. in chemistry.

University of Virginia, Charlottesville, Va.—The technical department of this institution is small, and out of 518 students attending the university the past year, only 14 were studying engineering. The university has a picturesque and healthful location among the foot-hills of the Blue Ridge mountains in the central northern part of the state. On Oct. 27, 1895, a fire destroyed the central building, known as the Rotunda. By this fire a large portion of the library was lost, but it is being rapidly restored, by contributions from individuals and other institutions of learning. The Virginia legislature has recently passed a bill through which it is expected that $200,000 will be realized for restoring the burned building.

Summer courses in law, chemistry and engineering are given, lasting eight weeks. The tuition fees are $50, $50 and $45, respectively.

The Leland Stanford Junior University, at Palo Alto, Cal., had, during the past year, 163 students in civil engineering, 125 in mechanical engineering and 85 in electrical engineering; the total number of students in the university being 1,069, 378 of whom were women. The total number of professors and instructors is 106. A summer school offers instruction in nearly all departments; the tuition is from $5 to $35. Tuition in the university proper is free.

The University of Minnesota,at Minneapolis, had an attendance during the past year in all departments of 2,467. The engineering department includes courses in civil, electrical, mechanical and mining engineering, also in metallurgy and chemistry. The requirements for admission are the same in all these courses, and include in mathematics only geometry and higher algebra. Shop work is required in none but the mechanical course; here it extends to the senior year, a total of 836 hours being required, which is an average of eight hours per week throughout the three years. The catalogue for 1897 contains 280 pages; a glance at the addresses of the students shows that a very large number are from Minneapolis.

Worcester Polytechnic Institute, Worcester, Mass. —President T. C. Mendenhall requests us to state that, by recent enactment of the state legislature, 20 new free scholarships become available to the next entering class. This makes 40 free scholarships in all available, being one for every senatorial district in the state, in addition to the 25 or 30 free scholarships to which students from Worcester county only are eligible.

University of Arizona, Tucson, Arizona.—This institution was opened in 1891; it has one main building, 105 × 200 ft., two stories high, a mining annex, 80 × 60 ft., and a number of small dormitories. It is situated about a mile from Tucson, on a 40-acre tract of land surrounded by attractive mountain scenery. Owing to the dryness of the climate and freedom from sudden changes this section has become quite a noted health resort. Tucson is 500 miles east of Los Angeles, at an elevation above sea level of 2,400 ft.

In engineering, the courses offered are civil, mechanical, electrical, mining and metallurgy, all leading to the degree of B. S. The whole number of students attending the university during the past year was 99.

Case School of Applied Science, Cleveland, O.—This school was founded in 1877 by Leonard Case and during the ten years in which Prof. Cady Staley has been its president the attendance has increased from 44 to 229. The mathematics required for admission are geometry and elementary algebra. Shop work, including joinery, pattern making and iron work, is required of all students in mechanical, electrical and mining engineering.

During six weeks of the summer vacation the laboratories will be open and instruction will be given in mathematics, chemistry and shop work. The catalogue contains a list of all the graduates which shows the majority to be holding excellent positions. Accompanying the catalogue is a separate pamphlet containing the president's annual report. It sets forth the progress of the school and devotes considerable space to rules for the government of athletics.

Agricultural and Mechanical College of Texas, College Station, Tex.—The twentieth annual catalogue contains 108 pages and 33 full page illustrations relative to the university and its special features. Arithmetic, English and History, constitute the reuqirements to enter the freshman class. These are four courses: Agriculture, horticulture, mechanical and civil engineering. The total number of students in attendance during the past year was 354.

IRON MINING on the Gobebic range has nearly ceased. The Tilden mine closed on July 31. It is stated that only 1,000 men are now working on the range where 8,000 are employed in busy times.

TRANSMISSION OF ELECTRICITY FROM NIAGARA FALLS TO BUFFALO.

For months past the press has contained numerous articles relative to the possibilities of the electricity generated at Niagara Falls. In fancy it has been transmitted to Chicago and New York, to there carry on all the various operations to which electricity can be applied. During this time, however, right of way has been secured for a transmission line between Niagara Falls and Buffalo. The construction of this line is alone estimated to cost $500,000. The poles will be of cedar and from 35 to 50 ft. long. The conductors will be of bare copper wire of 350,000 circular mills. We print a short description of the system.

The first step towards the actual transmission of the power of Niagara Falls over any considerable distance has been made, and Buffalo will be the first city to benefit by it. By Nov. 4 next, the cars of the Buffalo Ry. Co. will be driven by the electricity generated at the power house by the side of the great cataract, and the transmission of its power over a long distance will have become an accomplished fact.

Contrary to expectations, the system of transmission employed is not the two-phase, but the three-phase system, developed by the engineers of the General Electric Co., the advantage in favor of the latter lying in the fact that the transmission can be effected over three wires, whereas, in the two-phase, four wires must be used to convey the same amount of power. Thus the cost of the fourth wire is saved by the use of the three-phase system.

The contracts were made between the Cataract Construction Co., supplying the electricity, and the General Electric Co.; and between the latter company and the Buffalo Power & Conduit Co. controlling the supply and distribution of the Niagara power in Buffalo, and the Buffalo Ry. Co. The contracts provide for all the apparatus and machinery necessary for the transformation of, transmission, conversion and delivery of 1,000 HP. to the overhead wires of the Buffalo St. Ry. system.

The contract with the Cataract Construction Co. covers three of the air blast type transformers. These will be the largest transformers ever constructed, and will step-up the Niagara 2,200-volt two-phase current to either 11,000 or 22,000 volts three-phase. Any two of the transformers together will deliver 2,500 HP.; the third is a spare one. It is the intention of the Cataract Construction Co. to commence transmission operations at 11,000 volts, and later to increase the capacity of their transmission system by increasing the potential to 22,000 volts. The transformers will be designed and insulated to withstand the latter pressure. A complete system of air blast apparatus is also to be provided for cooling these transformers, as well as a marble switchboard with all necessary instruments for controlling their operation.

The pole line will be erected by the White-Crosby Co., and will have capacity sufficient to transmit 40,000 HP. This line will run from the transformer house at Niagara Falls along the two-mile line road near the track of the New York Central and Erie railways, will cross the creek at Division street, and from Tonawanda to the Buffalo city line will follow the canal banks.

For transforming the power down and converting it into that suitable for street railway purposes, the Power & Conduit Co. has purchased four static transformers of about 360 HP. each, and two 500 HP. rotary converters. The transformers will reduce from the line potential of either 11,000 or 22,000 volts to 400 volts, at which voltage the three-phase current will be turned into the rotary converters, and then converted into direct railway current of 550 volts. These transformers and converters will be set up in the Niagara street power station. The latter will be compound wound, and will operate in multiple with the steam-driven generators supplying the balance of the power necessary for the operation of the railway system. They will be of iron-clad type with steel frames, with collector rings for the three-phase current at one end, and a commutator for the direct current at the other. They will have six poles and will run at 500 revs. per minute, and are similar to that placed in the Niagara power house to furnish current to the Buffalo & Niagara Falls R. R.

Work will be begun at once and current will be transmitted from Niagara to Buffalo before winter sets in. It cannot be doubted that this is but the first step to a much larger use in Buffalo of the power of Niagara Falls, and that having once begun to deliver power into that city, the Niagara Power Co. will find a large demand for its output.

THE NEW U. S. LOCK AT SAULT STE. MARIE was informally opened for the first time at 10 a. m., Aug. 3. The first vessels to enter were the government boats "Hancock," "Andy Johnson," and "Antelope." The intermediate and upper lock gates only were used. Press dispatches state that the chamber was filled in about 13 minutes, not all the valves being opened at first, and it was emptied in 8 minutes. The gate machinery worked well, the lower gates closing in 3 minutes.

RENEWALS OF TIMBER RAILWAY BRIDGES WITH PERMANENT STRUCTURES.

In the report of the characteristics of the Lake Erie & Western R. R., made by Mr. W. F. Goltra, C. E. (Chief Clerk to the Chief Engineer), and representing the condition of the road on Jan. 1, 1896,* there is an interesting statement regarding the gradual substitution of wooden structures with permanent work composed of iron, steel or stone and filling with earth, for wooden structures.

On Jan. 1, 1887, there were 66,243 lin. ft. of bridges, all of which were wooden structures, with the exception of 523 ft. The permanent work then consisted of two iron girders, a few stone arches and stone boxes, 34 cast-iron pipes and 146 terra-cotta pipes. Since the present management took charge, on Feb. 1, 1887, permanent improvements have been made, gradually reducing the length of wooden structures from 65,720 to 31,037 ft., and permanent work has been substituted to the extent of 34,683.7 ft.; including 9,510.3 ft. of iron, steel or stone structures, and 25,173.4 ft. of solid earth embankment, thus shortening the aggregate length of bridges to the latter extent. Most of the costly structures have been built, and the average rate of $18.96 per ft. is higher than it will be for future permanent work, the cost of which is estimated at $15 per ft.

A few of the wooden structures were built in recent years and will not need renewal before six or seven years. It is estimated that the work of executing the permanent improvements will be completed by January, 1903, but as the annual appropriation for this work is dependent on the financial condition of the company, and also on the number of structures that require renewal, the estimated progress may vary somewhat. The estimated cost of completing the permanent structures is $420,000,000. Some wooden structures, to the extent of about 3,000 ft., may be renewed with wood owing to certain conditions that will not admit the economical substitution of permanent works, and the renewal of these is not included in the estimate. The length of bridging is being rapidly shortened by filling with earth, making solid embankments, and it is estimated that of the original 66,243 ft. of bridging on Jan. 1, 1887, about 45,000 ft. will be replaced with solid embankment, reducing the total length of bridging to 21,243 ft. by January, 1903.

Where iron pipe culverts, stone arches and boxes can be used, and the depth does not exceed 15 ft., the cost of permanent work is but little more than that of renewing wooden trestles, and seldom exceeds twice the cost, including the cost of filling openings with earth. For larger openings, where plate girders and masonry are necessary, the cost is little more than twice and seldom exceeds three times the cost of renewing wooden structures. The average life of wooden structures on this road is nine years. The cost of wooden trestles, not exceeding 15 ft. in height, is $7 per ft.; and that of wooden truss bridges is $28 per ft. Taking all the wooden structures into consideration, the average cost to renew them would have averaged about $9.90 per ft., while the permanent improvements will cost, when completed, an average of about $17.20 per ft.

Mr. Goltra says that if we view the question of cost from a financial standpoint only, and assume the interest at 5% on the investment for permanent improvements, the life of wooden structures at nine years, and average cost of same at $9.90 per ft., it is easy to calculate that it would be profitable to spend $3 for permanent work rather than to spend $1 for renewal of wooden structures, and as the ratio of cost for renewal of wooden structures and permanent work will only be about as one to two, the saving by making permanent work is apparent. But aside from this, what is saved by the reduction of openings in the track, thereby eliminating danger by fires, wrecks and accidents, is incalculable. The conclusion is, that if there is money available to make a roadway of permanent character at the earliest possible moment, it is certainly an element of economy in the operation of a railway to carry out such work as rapidly as possible.

---

*The first "characteristic" report made by Mr. Goltra was reviewed at some length in our issue of April 25, 1895.

THE NEW YORK RAPID TRANSIT COMMISSION on Aug. 6 decided to reject the application of the Manhattan Ry. Co., on the ground that it has no legal authority to grant permission for the construction of the surface railway lines which the Manhattan desires to build. It also adopted the following resolution::

> Resolved, That the Chief Engineer be, and he hereby is, directed to submit to this board at as early a date as possible routes and a general plan of rapid transit which shall conform to the following conditions:
>
> 1.—Total cost after abundant allowance for contingencies, not to exceed $30,000,000.
>
> 2.—Route to proceed from the southern terminus at or near the Postoffice and under the City Hall Park and Park row to Elm St. and Fourth Ave. to or near the Grand Central Station, and there to divide into the east and west side routes. The west side route to proceed under 42d St. to Broadway and the Boulevard to a point above 125th St. The east side route to proceed under Park Ave. and over private property to the Harlem River and across and beyond the Harlem River to as distant a point as the proposed limit of cost will permit.
>
> 3.—The railroad to have four tracks to the junction of the east and west side routes and above that point two tracks on each route, except that a third track for express service shall be added on both routes when conveniently and economically possible.
>
> 4.—The road to be in a tunnel, except on the east side, north of 98th St., and on the west side at Manhattan valley, 125th St.
>
> 5.—Plans to be so drawn as to permit further extensions in the future from the south and north termini and permitting the two and three-track portions to be widened into a four-track system without unnecessary expense or interruption of traffic.
>
> Resolved further That the Chief Engineer be authorized to call upon counsel of the Commission for such advice as he may deem necessary in the prosecution of the work hereby directed.

◆

THE TRACK DEPRESSION ON ATLANTIC AVE., in Brooklyn, N. Y., may be extended to the East River. We noted two weeks ago the estimate of cost submitted to the Commission in charge of the scheme, by the Long Island R. R. Co. Mr. Chas. M. Jacobs, Consulting Engineer to the railway company, has submitted the following additional estimate of the cost of depressing the tracks from Flatbush Ave. to South Ferry:

> To the Hon. Eugene G. Blackford, President Atlantic Ave. Commission, Montague St., Brooklyn, N. Y.
>
> Sir: In accordance with your request that I should consider the probable cost of extending the proposed depressed tracks of the Long Island Railroad westward from the present terminus at Flatbush Ave. to near the foot of Atlantic Ave. and South Ferry I beg to submit the following facts and estimate of cost:
>
> The length of the extension now suggested will be about 8,130 ft.
>
> This portion of the work will be more difficult of construction than that eastward of Flatbush Ave., and consequently more costly.
>
> The old Atlantic Ave. tunnel, from what I am able to ascertain, is of insufficient width to accommodate modern railroad cars on double-track service, is further constructed at such grades as to be of little service other than as a deduction for quantity of excavation already executed. This item is allowed. I am of opinion that if this plan were adopted it would be necessary to put in a station near Hoyt or Smith St. and have included this in my estimate. The question of a station for terminus at the foot of Atlantic Ave. I find is a large one, and it is impossible to estimate the cost of this work until the location of the terminus can be decided upon.
>
> My estimate of the cost of a two-track road for this extension, exclusive of diversion of sewers, water mains, etc., and of paving the surface of streets, and exclusive of relaying trolley car tracks, etc., is $1,188,058.
>
> Yours truly, Charles M. Jacobs,
> Consulting Engineer.

◆

COMPRESSED AIR MOTOR CARS are to be put in service on the Eckington & Soldiers' Home street railway in Washington, D. C. The cars are to be built by H. K. Porter & Co., of Pittsburg, Pa.

◆

THE LOUISVILLE WATER PURIFICATION EXPERiments were completed on July 31, but the report on the same is yet to be prepared. These experiments were begun about Oct. 1, 1895, and are the most extensive and careful tests of the kind ever made in this country. Four different processes have been tried, each being operated, as we understand it, at the rate of at least 250,000 gallons a day. The processes have all been patented ones, and the plant for each system has been operated by representatives of the company controlling it, the water being delivered to the filters without charge to the companies. The details of the tests have been under the general supervision of Mr. Chas. Hermany, M. Am. Soc. C. E., Chief Engineer of the Louisville waterworks, with Mr. Geo. W. Fuller as chemist and bacteriologist in charge. Mr. Fuller has had a large force of assistants, as his work has involved the collection and examination of a large number of samples. The Western Filter Co. had both gravity and pressure mechanical filters, each of 250,000 gallons daily capacity; it was represented by Mr. Chas. T. Whittier. The O. H. Jewell Filter Co., of Chicago, and the Cumberland Manufacturing Co., of Boston, the latter making the Warren filter, each had a gravity filter of 250,000 gallons capacity; the Jewell filter was in charge of Mr. Ira H. Jewell, and the Warren of Mr. Geo. Albert Soper. All of the plants named above were installed in 1895, we believe. The fourth process was started in March, 1896, by the John T. Harris Magneto-Electric Purifying Co., of New York, and was in charge of Mr. Harris. This process, so far as can be learned, relies first upon the partial electrolytic decomposition of the water, said to have an effect somewhat akin to the use of a coagulant, with a subsequent removel of suspended matter by some mechanical means, sedimentation or rapid filtration. Mr. Chas. R. Lang is President of the Louisville Water Co., the stock of which is practically all owned by the city.

◆

A NEW SCHEDULE OF WATER RATES at Keokuk, Ia., is to be established on the basis of the cost of building a plant equal to the existing one in efficiency and extent, if present plans are carried out. The works were built by the Keokuk Water-Works Co. in 1877-8, under a 20-years' franchise. Mr. Jacob A. Harman, of Peoria, Ill., has been engaged by the city to make the necessary estimates.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week was a derailment of a freight train at Leighton, Ia., on the Keokuk & Des Moines branch of the Chicago, Rock Island & Pacific R. R. The train was an extra eastbound, and the derailment is said to have been due to the breaking of an axle on the fifth car from the engine. The number of men killed is variously reported at from three to seven.

◆

A FREIGHT TRAIN COLLISION on the Louisville & Nashville R. R. at Mountain Creek, 68 miles south of Birmingham, Ala., on Aug. 1, is said to have been due to the engineer of one of the trains going to sleep in his cab, and running past the point where his orders required him to stop to await the passage of the other train. Two men were killed.

◆

A BURNING TRESTLE on the Oxford & Clarksville R. R., 10 miles from Durham, N. C., caused a train wreck on Aug. 2. The engineer and fireman were injured but the other trainmen and the passengers escaped.

◆

AN ELECTRIC CAR RAN AWAY on a steep grade of the Columbia & Donegal Electric Ry., near Columbia, Pa., on Aug. 9, and 6 persons were killed and 62 injured. The car was heavily crowded, and for some reason the motorman lost control of it while descending a heavy grade. The car at once attained terrific speed and jumped the track at a sharp curve at the foot of the hill and ran across the turnpike for a hundred yards, it then struck a train of cars and turned on its side in a deep ditch.

◆

A BRIDGE WAS BLOWN DOWN near Thomaston, Ga., on Aug. 3. According to press dispatches, it was an "improved lattice suspension bridge 250 ft. long and built at a cost of $700."

◆

A HEAVY RAINSTORM visited Richmond, Ind., on Aug. 8. A correspondent informs us that the rain began falling at midnight, Aug. 6, and continued for ten hours, the total precipitation being 5.9 ins., of which 3.9 ins. fell between 4 a. m. and 10 a. m. Many bridges were swept away and part of the east abutment of the National bridge over the Whitewater River, built in 1834, and forming part of the old National turnpike, was destroyed.

THE RESPONSIBILITY FOR THE ATLANTIC CITY accident will probably have to be settled in the courts, unless the two railways concerned can reach an agreement as to the proportion of damage that will be borne by each. Nearly all the deaths and injuries were to passengers on the Pennsylvania train; but the accident was caused by the engineer of the Reading locomotive.

◆

A SWING-SPAN BRIDGE WAS WRECKED at Milwaukee, Wis., on Aug. 3, by being run into by the whaleback passenger steamer "Christopher Columbus." The bridge is located at Buffalo St. It was being opened to permit the passage of the steamer, but the difficulty of manoeuvring the boat in the narrow channel was such that the vessel struck one end of the span when it had been swung about three-quarters open. The span was pushed off the turntable, and according to newspaper reports, narrowly escaped going over the side of the pier and into the river. The "Milwaukee Wisconsin" argues as the lesson of the accident, that swinging bridges are out of date as draw-spans over narrow channels.

◆

A PECULIAR ACCIDENT occurred at the Brooklyn Navy Yard on Aug. 8. The caisson closing the entrance to dry dock No. 2 gave way when the dock was empty, and the rush of water into the empty dock tore a half-dozen vessels loose from their moorings and did much damage to several of them. According to newspaper reports, some repairs were in progress on the interior of the caisson, and to facilitate the work a large proportion of the rock ballast with which the caisson is loaded had been removed, With the incoming tide, the buoyant effect of the water on the outside of the caisson became so great as to lift it from its groove, and the water, which was 26 ft. on the outside, of course immediately filled the dock.

◆

THE SOUTHAMPTON-NEW YORK TRANSATLANTIC record was broken by the "St. Louis," of the American line, which reached Sandy Hook light-ship at 11.26 a. m., Aug. 7, having made the passage from The Needles in 6 days, 2 hours and 24 minutes. The ship sailed 3,055 knots and made an average speed of 20.867 knots. The daily runs were, 477 knots, 519 knots, 530 knots, 520 knots, 510 knots and 499 knots. The captain is said to have stated that there was a fog on two days lasting 16½ hours and another when near New York of 5 hours, had it not been for which he would have made still better time. In the light of the above record of daily runs it can be appreciated how much (or little) a transatlantic greyhound slows down for fog.

◆

A NEW TRANSATLANTIC FREIGHT STEAMER is to be built by the Hamburg-American Steamship Co.,and will be called the "Pennsylvania." According to newspaper reports, it will have a length of 568 ft., beam of 62 ft. and 42 ft. depth. Its displacement will be about 20,000 tons. It will be propelled by quadruple expansion engines of 7,000 HP., and will carry 13,000 to 14,000 tons of freight, 228 cabin passengers and 1,500 steerage passengers. It is claimed that she will be the largest freight steamer afloat.

◆

ONE OF THE NEW LAKE FREIGHT STEAMERS, which has just been put in service is "The Senator," built by the Detroit Dry Dock Co., for the Wolverine Steamship Co. The vessel is 424 ft. long over all, 45 ft. 6 ins. beam, and 28 ft. deep. Her tonnage is 4,048 gross and 3,178 net. She is driven by triple-expansion engines with cylinders 22, 35, and 58 ins. and 44 ins. stroke. Forced draft is used and a speed of 14 miles an hour was made on the first trip.

◆

EIGHT GAS-LIGHTED BUOYS are to be placed in the St. Lawrence River, between Ogdensburg, N. Y., and Cape Vincent. Each holds 176 cu. ft. and burns for several months without refilling. The buoys were furnished by the Safety Car Heating & Lighting Co., of New York city.

◆

PROPOSALS FOR EXTENDING THE HYDE PARK water supply tunnel at Chicago, are wanted until Aug. 18. The extension will be 7 ft. in diameter and 5,300 ft. long. Mr. Joseph Downey is Commissioner of Public Works.

◆

BIDS FOR SORTING THE RUBBISH of the city of New York, other than garbage, ashes and street sweepings, are to be received by the Department of Street Cleaning, of which Col. Geo. E. Waring, Jr., M. Inst. C. E., is Commissioner, until Aug. 26. The material will be sorted at the yards of the department, as brought there by the department. The contract will run for a year and the contractor will pay for the privilege weekly in advance.

◆

A SHORE DRIVE FOR BROOKLYN is to be constructed soon, after plans by Olmsted, Olmsted & Eliot, Landscape Architects and Engineers. It is said that the drive will be three miles in length, extending from Bay Ridge to a point near the U. S. Military Reservation at Fort Hamilton. Mr. Elijah R. Kennedy is president and Mr. Geo. Ingram is secretary of the Shore Road Commission, whose office is at the City Hall, Brooklyn, N. Y.

LOCKS AND DAMS ON THE GREAT KANAWHA RIVER, W. VA.

The Great Kanawha of West Virginia is one among the many navigable rivers of the United States which is being improved by the government under appropriations made in the River and Harbor bill, and expended under the U. S. War Department and its corps of engineers. The figures and statements hereafter given will show that the money on this particular stream especially, has been wisely expended, and the results attained are entirely satisfactory.

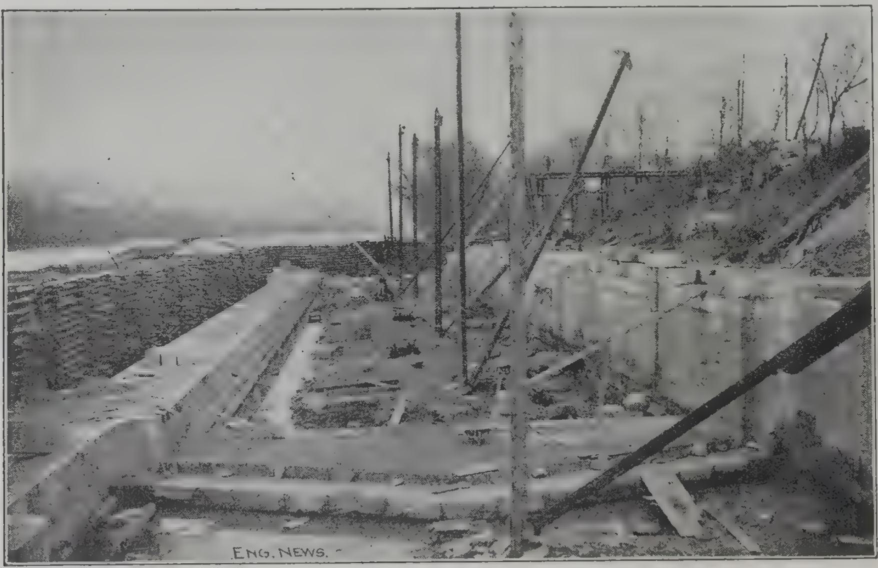

FIG. 1.—LAYING THE MASONRY FOR LOCK NO. 9, GREAT KANAWHA RIVER. Zimmerman, Truax & Sheridan, Contractors.

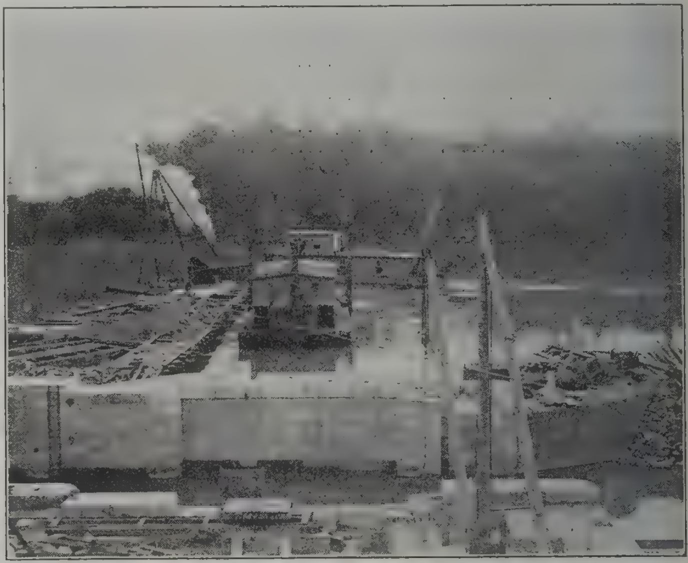

Fig. 3.—Lock Nearly Completed. Coffer Dam for First Section of Dam Begun.

This stream is a continuation of New River, which takes its rise in Watonga Co., N. C., and is joined by the Gauley, of West Virginia, near Kanawha Falls; the distance from there to its mouth, where it empties into the Ohio River, 260 miles above Cincinnati, is about 100 miles. The river flows through a fertile and picturesque region filled with coal, salt and timber.

Originally the stream could not be depended on for navigation purposes, as at some seasons of the year the water was extremely low and many snags and loose rocks were found in the channel.

Something was done by state aid to remedy the trouble, but the results were very intermittent and unsatisfactory, as little could be accomplished except in high water.

Finally, suitable appropriations were obtained and the government undertook, by means of a complete system of large locks and dams, to obtain a constant navigable depth of at least 6 ft. throughout the whole length of the river. This necessitated the building of ten locks and dams, and locations were selected at suitable points that would give the desired result. Dams Nos. 2, 3, 4, 5, 6, 7 and 8 are already completed and in successful operation, and Nos. 9, 10 and 11, to complete the system, are well advanced, as shown by the illustrations.

In January and February, 1893, the Engineering News contained advertisements for the work, and on Feb. 16 of that year the bids for lock and dam No. 9 were opened at Charleston, W. Va. Zimmerman, Truax & Sheridan, contractors, of Duluth, Minn., were the lowest bidders, and a month later the contract for dam No. 10, situated 6½ miles further down the river, was awarded to the same firm, and about the same time No. 11 was also placed under contract with Mr. Thos. Mumford.

The photographs herewith published were taken at lock 9, and gives a good idea of the progress of the work at each place, all being at practically the same stage of advancement.

Fig. 1 shows the manner of conveying and laying stone, prior to the removal of the coffer dam around the lock walls, by means of a tramway on the tipple shown on the land wall side of the cut. The stone and material, from the railway siding and stone cutting yard on top of the bank, are conveyed and then lowered by a derrick onto tram-cars which run on a track to the point of the wall where the material is needed. Fig. 2 shows the wall after the removal of the coffer dam, and the manner of setting stone with derrick boat. The material in this case is lowered onto barges instead of tram-cars and then floated to the point needed. Fig. 3 shows the lower end of the lock walls, part of the protection crib, and the commencement of the coffer for the first section of the dam, with dredges at work. This section is 270 ft. long, 97 ft. wide. The total length of dam when completed is about 500 ft. Fig. 4 shows the completed coffer with channeler drill cutting trenches in the bed rock for anchor bolts, to be set about 9 ft. deep in concrete.

All the locks below Charleston are uniform in size, being 411 ft. in total length of masonry, 342 ft. long between quoins and 55 ft. wide in the chamber between walls. The walls at Lock No. 9 are 19 ft. above top of miter sill and 25 ft. above bed rock. Those at No. 10 are but 21 ft., as the bed rock lies higher.

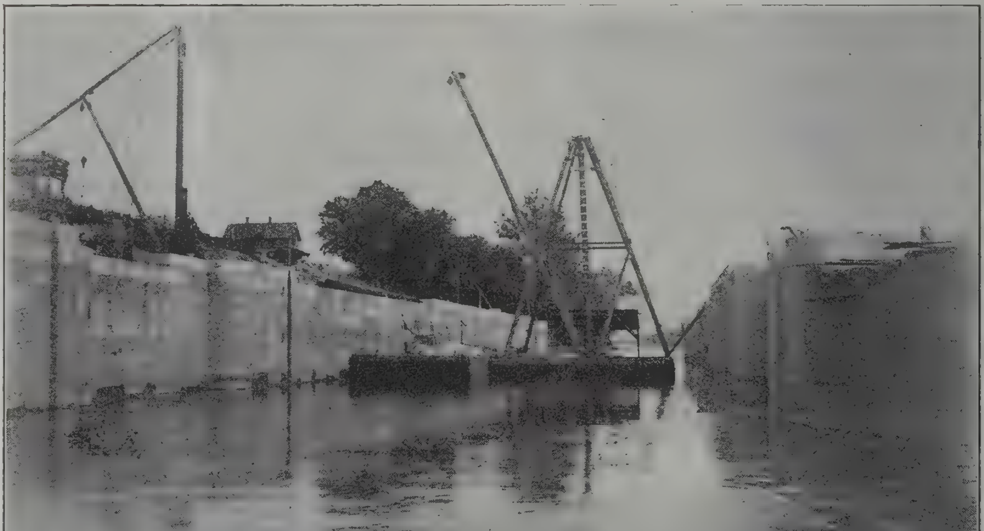

FIG. 2.—LAYING STONE FROM BARGES TO COMPLETE LOCK

The approximate quantities for Lock and Dam 9, with contract price received, are given as follows:

Kind of work Lock and dam 9:	Approximate quantities.	Bid.	Amount.
Grubbing and clearing	complete	$500.00	$500
Crib logs in cofferdam	140,000 ft.	.17	23,800
Sheathing	93,000 ft. B.M.	25.00	2,325
Cofferdam filling	21,500 cu. yds.	.65	13,975
Excavation	44,000 " "	.80	35,200
Excavation, rock	800 " "	2.00	1,600
Embankment	10,500 " "	.55	5,775
Puddling	1,300 " "	2.00	2,600
Concrete	2,500 " "	6.75	16,875
Backing masonry	5,950 " "	9.00	53,550
Rock-face masonry	2,970 " "	11.00	32,670
Pointed-faced masonry	2,200 " "	13.00	28,600
Cut-stone masonry	450 " "	18.00	8,100
Sills	520 " "	17.00	8,840
Quoins	76 " "	24.00	1,824
Coping	870 " "	18.00	15,660
Stone filling	4,200 cu. yds.	2.00	8,400
Riprap, hand-placed	3,000 " "	3.00	9,000
Paving	1,100 " "	5.00	5,500
Timber, perm. const'n.	165,000 ft. B.M.	40.00	6,600
Bolt holes in masonry	6,500 lin. ft.	.30	1,950
Total			$283,344

The quantities at No. 10 are somewhat smaller, the prices received averaging 7½% higher, and the total building price was $232,44[illegible]. At No. 11, owing to increased depth of foundations, the quantities are considerably larger, the total price amounting to a little over one-half million dollars.

As regards the class of work, the courses of masonry ranged from 1 ft. 6 ins. to 2 ft. 2 ins. in thickness, and the stones averaged about 1 cu. yd. Some of the larger ones, however, slightly exceeded 2 cu. yds. in contents. The inside faces of the lock chamber were vertical and built of "point face" and cut stone. The outside of the river wall was "rock face," with a batter of 3½ ins. to the foot from foundation to the top of the coping. The wall facing the land was made of selected backing, with each course set in from 5 to 7 ins., according to the height of the course. Immediately back of this wall was a rock drain, 3 by 8 ft., extending the whole length of the wall and intended to carry off the surface seepage and the water of some springs. The outlet was in the lower wing wall. The bed rock, especially at Lock No. 9, was very hard and uneven in places, and the projections were all carefully removed and the foundation stone well fitted to the level surface, so as to prevent water coming through under the wall. Sheet piling and clay puddle were required to cut off water from springs in the bank and the quicksand that came with the water.

Work was commenced at each place at about the same time, in July, 1893, and has been continued without stoppage to the present, except when interfered with by floods, or bad or frosty weather. No masonry is set after frost appears and the open season generally commences about June 1 and ends the latter part of November. No fatalities have occurred and but few minor accidents since the work was started.

Owing to the liability of sudden and violent rises in the river, the coffer dams used are made unusually strong; that at No. 9, enclosing the lock walls, is 542 ft. long up and down stream with shore ends 114 ft. each, or 770 ft. in total length, and 21 ft. high above bed rock. It is made of rough green timber about 7 ins. in diameter made into cribs heavily drift-bolted, 16 ft. wide and 21 ft. long. It was sunk in sections to bed rock, the trenches having been excavated by dredging, and the cribs then filled with heavy dredged material, sheathed with boards and banked with clay and gravel to a natural slope. The banking and filling are then riprapped on top with rough stone to protect them from the wash. Built in this manner they have never given trouble although subjected to the most extreme tests. In the fall of 1893 the dam was flooded and pumped out five times, and on one occasion, in 1894, there was a rise of 19 ft. in as many hours, causing heavy currents but resulting in no injury whatever to the coffer dam.

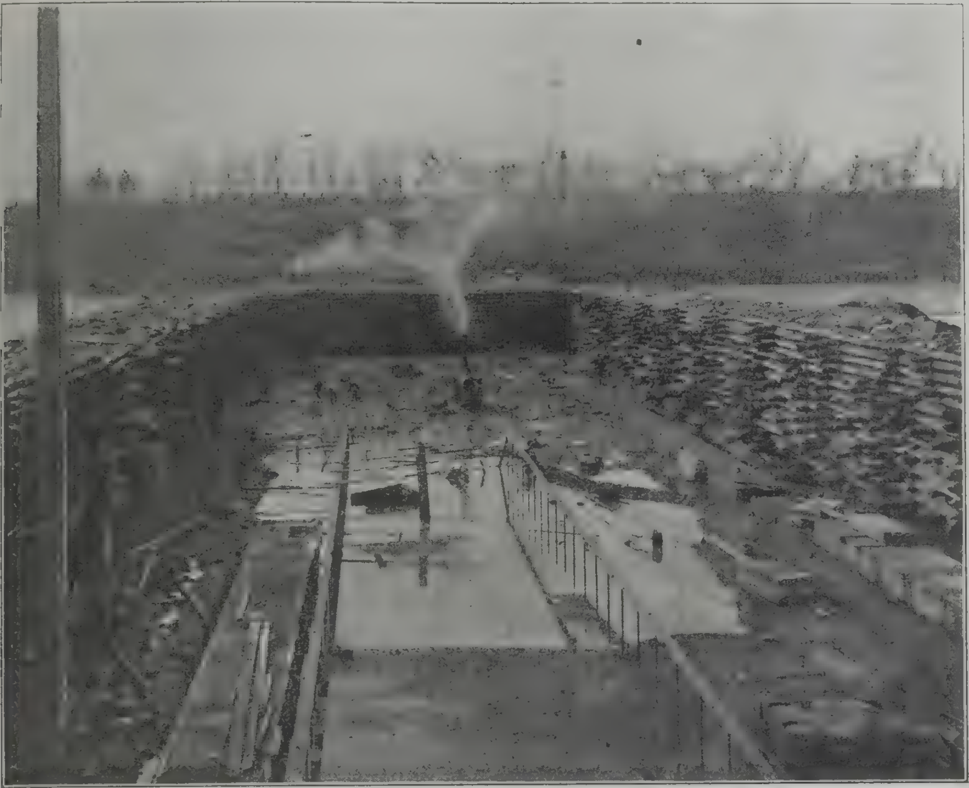

FIG. 4.—COFFER DAM COMPLETED AND PUMPED DRY, AND WORK IN PROGRESS ON DAM FOUNDATIONS.

The plant used by Zimmerman, Truax & Sheridan consists of:

1 Bucyrus 2-yd. dipper dredge, having steam speed hoists, independent swinging engines and steel boom; 1 Marion, O., 1½-yd. dipper dredge; 1 Wardwell channelling drill; 1 Sergeant-Ingersoll steam drill; 1 Lidgerwood carrier, 200 ft. span, used at quarry to convey and load stone on railway cars for transportation; 3 steam derricks or crane boats with 70-ft. booms; 2 large dump scows; 2 pumps, boilers and engines, with Baldwin's Centrifugal pumps; 8 working barges; 2 blacksmith and machine shops; 2 commissary stores; side tracks; cement houses, etc.; 25 derricks, either steam or doubledrum boom-hoisting horse power. In connection with this plant over five miles of ⅞-in. galvanized iron guy line and steel hoisting line were used. The wire rope was purchased principally from Jno. A. Roebling & Sons, and derrick fittings, engines and horse powers from the American Hoist & Derrick Co., St. Paul, Minn.

At No. 11 the lock is on the opposite side of the river from those at 9 and 10, and the material is carried across the stream from the railway siding by a Lidgerwood cableway having 2½-in. main cable, the distance between towers being 1,505 ft. The lowest part of the cable, without load, is 94 ft. above low water and it carries a maximum load of 4 tons and has worked very satisfactorily.

The stone used is a native sandstone, obtained chiefly at Lottes, W. Va., near the river, 20 miles above Lock 9. Stone for the other locks previously built has also been obtained at that point or elsewhere near the river, and has generally been satisfactory to the engineers as to strength and wearing qualities, but some difficulty has lately been found in fully satisfying the authorities. This is caused largely by the requirements for coping stone, which are of large size, as between the gate recesses on both walls for a distance of about 600 ft. all headers are used, none less than 2 ft. 6 ins. wide, 1 ft. 6 ins. thick, 6 ft. long on lock wall, and 6 ft. 11 ins. on river wall. These must be perfect in weight and texture and without flaw or defect.

The inspection and management of all the work has been under the immediate supervision of Mr. A. M. Scott, M. Am. Soc. C. E., Resident Engineer, Charleston, W. Va. There has been a rigid enforcement of specifications and close attention to minor details The chief inspectors in immediate charge of construction at the different points are Thos. E. Jeffries, C. E., and J. R. Myers, for Lock 11. A. M. Campbell, C. E., and Saml. Campbell, for Lock 10, and R. M. Stephens and Walton Venable for Lock 9.

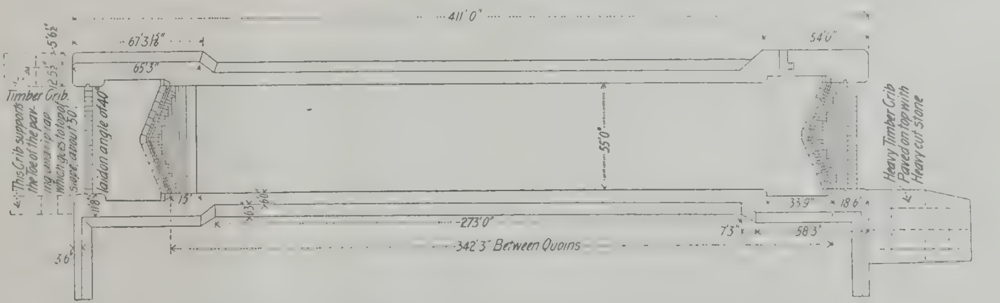

FIG. 5.—PLAN OF LOCKS NOS. 9 AND 10, GREAT KANAWHA RIVER.

The cement used is the Ulster Co. brand, or Hoffman brand of Rosendale, mixed 2 parts of sand to 1 of cement, except in foundations where it is used 1 to 1. Coping and cut stone were cut to ⅜-in. joints; other face stone to ½-in., and backing-bed and outside vertical joints to 1 in. The average amount of cement used was about one barrel or 300 lbs. to 2¾ yds. of masonry, and all the work has been first class in every particular.

The dam used, except at Nos. 2 and 3, which are fixed or stationary, is the Chanoine wicket type, operated by trestle service bridges. The sills of the navigation pass are from 12½ to 13 ft., and the sills of the weir from 5 to 9 ft. below upper pool levels. They have worked satisfactorily and with comparatively small expense. These dams can be lowered when the stage of water in the river will suffice over the shoals, this making an open river when the water is high enough.

The obstruction on account of ice averages but 9 days per year; while in some of the recent floods it was found impossible to ship full loaded coal barges drawing 6 ft., more than 100 days in the year. On the completion of the contracts herein mentioned this delay will be entirely obviated and a constant gage of at least 6 ft. will be maintained and with it a proportionate increase in the river traffic which for 1894 is itemized as follows:

Articles.	Quantity.	Tonnage.
Coal	25,821,000 bush.	1,032,840
Timber	19,648,000 ft. B.M.	32,920
Staves, oak	501,000	1,500
Tanbark	880 cords	880
Hoop poles	115,000	230
Railroad ties, oak	580,860	87,130
Shingles	2,067,000	310
Brick	888,000	2,220
Salt	3,180 bbls.	440
Merchandise and produce on steamboats		64,000
Total, 1894		1,222,530
Total tonnage.		
1890 (report of Chief of Engineers, p. 2,246)		1,127,232
1891 (" " " " " 2,425)		1,225,355
1892 (" " " " " 2,062)		1,360,750
1893 (" " " " " 2,593)		1,116,537

There has been an increase, since 1877, of 20,637,000 bushels of coal alone.

The total expense to the government for the completed work, including superintendence and operating expenses, will approximate $4,000,000, and the expense of operating and keeping each lock and dam in repair will approximate $2,700 per year.

For information contained herein we are indebted to the reports of the engineers having this work in charge, and to the contractors for the material from which our illustrations are prepared.

REDUCTION OF THE WEIGHT OF RECIPROCATING PARTS IN LOCOMOTIVES.*

(With inset.)

It is not the intention of your committee to discuss extensively the necessity for reducing the weights of reciprocating parts. While locomotives were yet light in weight, and low boiler pressures and moderate speeds were the rule, the effects of improper counter-balancing were not serious, and consequently the matter received but scant consideration.

The great increase in the size and weights, and also in the boiler pressures of locomotives which had been made during the past ten years, to meet the demand for greater hauling capacity and higher speeds, has made it necessary to largely increase the size and strength of most of the parts. The increase in mass and strength has, perhaps, made the locomotives more capable of absorbing without injury to themselves, the greater portion of the disturbances caused by the reciprocating parts, but the numerous reports of damaged tracks, bent rails and broken bridges that have been caused by badly balanced engines, the now common practice of high maximum speeds and the introduction of the compound locomotive, with its large reciprocating weights, have all served to attract attention to this subject.

The result has been that probably during the past few years more thought and study has been given to this subject of counter-balancing than in all the previous history of the locomotive. That the matter has received careful attention is evidenced by the able reports that have been made to this Association and the valuable papers that have been read before the railway clubs and other societies, as well as the numerous articles that have appeared in the technical papers, so that the whole question is to-day better and more generally understood than ever before, and there is no point that has been more clearly brought out than that of the great desirability of reducing the weight of the reciprocating parts to the lowest possible limit consistent with necessary strength.

---

*Report of a committee of the American Railway Master Mechanics' Association, presented at the Saratoga convention.

In seeking to accomplish this there are but two conditions that can properly be considered—material and design—and we shall consider them as applied to the parts under discussion.

Pistons.

The use of cast iron for pistons has been almost universal in this country, principally because they can be easily and cheaply made of this material, and also because of the low cost of maintenance and renewal. Cast iron is not only relatively a weak metal, but the stresses due to uneven contraction in cooling necessarily compels designers to make cast-iron pistons stronger than would theoretically be needed to resist only the external forces; also, in spite of the many advantages cast iron has over other iron and steel for piston material, the allowable stress cannot be great. A comparison of the relative strength and cost of mild or soft steel and cast iron would seem to indicate that the substitution of steel, either cast or in plate form, forged or pressed, or perhaps a combination of both, would offer the most practical solution of the problem of how to effect a saving in weight here without unduly increasing cost; and your committee find that much progress has been made in the use of this metal for pistons, and in most cases a large reduction in weight has been the result.

In design, the single plate form seems thus far to have been the most in favor, and undoubtedly this type permits of the greatest possible reduction in weight consistent with a proper degree of strength. For very large pistons for the low-pressure cylinder of compound engines, it is certainly to be preferred to any type that has yet been brought out. Three forms of this kind of piston are made, viz., with central plate, a very good example of which is shown in Fig. 1; the side plate as per Fig. 2, and the inclined, or Z form, as per Fig. 3.

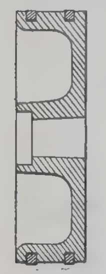

Fig. 2.—Side Plate Piston for Locomotives.

A modification of the side plate is heavily dished and provided with a cast-iron rim, as shown in Fig. 19.

Although the single plate solid-cast or forged steel piston probably presents the best form for combining strength and lightness, the wear between piston and cylinder, due to the greater coefficient of friction, presents an objection to its use which it has been sought to overcome in various ways; and further, when the cylinder has been worn to such an extent that reboring is necessary, and the piston is consequently too small, your committee could not learn that any satisfactory method had yet been devised for enlarging it, consequently the whole piston must be thrown away. Several plans have been tried for providing the rims of steel pistons with a bearing surface of metal having better wearing qualities and that would be less liable to damage the cylinder than steel. In some instances the surface of the rim has been tinned all over to a depth of 1-16 or ⅛ in., but the tin does not hold well. In the piston shown in Fig. 4 the Richmond Locomotive Works has tried grooving the rim as shown, and then filling the grooves with tin, but this was not a success. Brass or bronze has been cast in the grooves, putting in a section, allowing it to cool, and then burning or casting on another section, thus providing for shrinkage. This plan has proved more successful, but owing to its necessary limitations, large wearing surfaces cannot be obtained; and the wear is consequently rapid, and repairs must be frequently made. In the piston designed by Mr. F. J. Cole, for the Baltimore & Ohio Railroad, and shown in Fig. 3, the two packing rings are made quite wide, but while they would possibly better meet the requirements for wear, such wide packing rings are usually considered objectionable.

Fig. 5 shows a Z plate piston made by the Rogers Locomotive Company, in which the wear seems to be very well provided for. It is designed for compound locomotives with 19-in. or 20-in. diameter horse-power, and 29-in., 30-in. and 31-in. diameter low-pressure cylinders. These all have a cast-iron "carrying-ring," AA, as shown on their face. The piston is turned to shape to receive this ring, and the latter bored to fit, sawed through at one place, sprung on and secured from turning by ½-in. copper rivets. The grooves for packing rings are then trued up to size, the edges of the carrying ring A furnish in part the bearing for the inner edge of the packing rings. As A is slightly larger in diameter than the flange of the piston, at the outer side of the packing rings, the cast steel part will not touch the cylinder until A is worn down about 1-16 in.; A can then be turned with its worn face to the top by removing the copper rivets and putting in new ones, their holes being drilled by templates to match again when A is turned 180°.

Weight of 20-in. diameter piston, with rod, Fig. 5, 358 lbs.; 31-in. diameter, complete with rod, 535 lbs.

Figs. 6 and 7 illustrate a very handsome, strong and light design for cast steel single plate pistons, and which is used in Class "K" two-cylinder compound built by the Chicago, Burlington & Quincy Railroad. Eccentric spring packing rings of cast iron are lined solid on the bottom, 12 ins. of the circle in high pressure cylinder, and 18 ins. in the low pressure cylinder. The low pressure piston rod is extended through and supported by the front cylinder head. To reduce as much as possible the weight of this extension it is made of steel pipe, which is internally threaded and screwed on to a short extension of the rod. These pistons were designed for 180 lbs. steam pressure, and weigh as follows:

Weight 20-in. cast steel piston (Fig. 6)	221 lbs.
" piston rod	94 "
" 3-in. nut	5 "
Total	320 lbs.

Weight 29-in. cast steel piston (Fig. 7)	395 lbs.
" solid rod	94 "
" hollow extension rod	46 "
" 3-in. nut	5 "
Total	540 lbs.

The Pennsylvania Railroad has designed and is using a piston which is shown by Fig. 19, and which is a combination of a single plate, dished in shape, cast or forged steel, and a cast-iron rim secured to the plate by countersunk head screws. The rim is made much the widest at the bottom, where it bears on the cylinder. This design combines the lightness and strength of the Z-plate, with the additional advantages of a good wearing surface and ease of renewal.

One objection to this design is that if great care is not exercised in fitting up the pistons, there may be leakage around the bolts. The rings must be nicely fitted and drilled to jigs, holes tapped and bolts well threaded and made steam tight. After bolts are screwed up, they should be tightly riveted up, care being taken that they are not loosened in the operation. These pistons have been in service about two years with good results.

The designs in single-plate pistons, which have been mentioned and illustrated, have been made principally for high speed and high pressures, and are given as good examples of what can be done where it is very desirable to reduce the weight to the lowest possible limit consistent with strength, the question of cost being secondary. With this type of piston, in order that the clearance spaces may not be too great, it is necessary that the shape of the cylinder heads should be made to conform to that of the piston, and it is recommended that the surfaces of pistons and cylinder heads should be turned all over, although this is not absolutely necessary, providing the work of casting and fitting up the parts is well done.

There are many who favor the bull-ring type of piston, because they believe that this form, while presenting good wearing surfaces to the cylinders, also enables the wearing parts to be easily and cheaply renewed, and repairs can be quickly made. Also this type enables the Dunbar or other sectional packing rings to be used; further, with this form of piston, as with solid piston, it is not necessary to cast irregular-shaped and excessively heavy cylinder heads, and the clearance spaces are more easily regulated. By the use of steel this type of piston can be much lightened. Fig. 8 shows a design of steel piston of the bull-ring type, which has been successfully used in engines built by the Schenectady Locomotive Works. Referring to the design, Mr. A. J. Pitkin, the superintendent, says "We make extensive use of the I-section form of piston (Fig. 9) where roads desire solid heads. When the separate bull-ring and follower type of piston is desired, we are using the design shown (Fig. 8), making the spider and follower of steel, and we have found this makes a very strong and light piston, and one which gives good satisfaction in service."

The weight of piston and rod in Fig. 8 is 318 lbs., including rod and nut; weight of piston and rod, Fig. 9, 299 lbs.

Fig. 10 shows a 20-in. solid or box piston, blue print of which was furnished your committee by the Norfolk & Western Railroad. This is made of malleable iron, and is very interesting as showing the possibilities of the application of malleable iron in the construction of light pistons. The report of Mr. G. R. Henderson, mechanical engineer of this road, to Mr. R. H. Soule, superintendent of motive power, copy of which was sent with blue print, gives results of a test made of this piston in comparison with a solid-cast iron piston. Report states that pressure was first applied to center of malleable portion to try strength of brass retaining ring, and at seventy-eight tons on wheel press the outer cast iron wearing ring broke, the malleable iron center being only slightly damaged at edges. The piston was then put on wheel drop, supported on a cast-iron ring around the outer edge, given fifty blows with 140-lb. drop falling 12 ft. This merely curled up the edges somewhat, and it was then taken to a casting breaker and given one drop of 5 ft., one of 8 ft., one of 12 ft., and two of 18 ft., when it broke badly. The solid cast-iron piston cracked at ten blows of a 140-lb. drop, and went all to pieces on the fourteenth blow, showing that the malleable piston was much the stronger. In service the pressure tending to force off the outer ring would only be the steam pressure multiplied by the area, about 15,000 lbs., which gives a factor of safety for that portion of about 10. The cast-iron piston weighed 257½ lbs., while the composite weighed but 187½ lbs., a gain of 70 lbs. Mr. Henderson thinks that this type, having shown such remarkable results, can be still further reduced in thickness, thus further reducing the weight, and he expects to make other experiments with this end in view.

Fig. 11 shows another type of malleable iron piston, blueprint of which was received by your committee from the South Carolina & Georgia Railroad. Two of these pistons were placed in a 17 × 24-in. passenger engine about four months ago, and have given good results; have been removed on two occasions for examination and found in good condition, and contained no condensed water. The weight of piston, with rod, is 175 lbs. as against 265 lbs. weight of old rod and piston of the bull-ring and follower type. This is a difference of 90 lbs. for each piston, a saving that would seem to argue well for the further use of this material for pistons.

Piston Rods.

Piston rods have always had a circular section, and no other section can be had as good for the same purpose. Iron has been very largely replaced by steel. The only way that the weight of this part can be reduced is to make the rod hollow, plugging the ends to prevent steam from coming through. A design for hollow rod is shown in Fig. 12, and is submitted by the Schenectady Locomotive Works, which states that it has not yet used this design. Its latest practice is to make the ends or fits larger than the body of the rod, which enables it to make the rod lighter than if the crosshead fit was made in the usual way, and also diminishes the risk of breakage. This practice, in connection with the hollow rod, would give the lightest possible form. We find that it is now the almost universal practice to secure the piston to the rod by a single nut, instead of keys or pins, as was formerly done. This is no doubt largely due to the increase in steam pressures which has been made during the past few years, and which has rendered desirable a safer and more reliable form of construction.

Mr. E. M. Herr, assistant superintendent of motive power, Chicago & Northwestern Railway, sends drawing of piston rod used on that road, and which has crosshead fit 3½ ins. diameter, while body of rod is 3¼ ins. diameter, and says: "This is not only done to lighten the rod, but to make it stronger where the strength is needed." He also says: "I am of the opinion that with the proper material we can use hollow rods to good advantage, and I am now looking this matter up with a view of trying a set experimentally."

Crossheads.

The substitution of steel for cast or wrought iron would seem to offer the most promising method of reducing the weight of crossheads, and your committee finds that in several recent designs for high-speed locomotives, as well as heavy freight locomotives, this metal has been employed with good results. Fig. 13 shows a design of crosshead of the four-bar guide type, which is probably as light as it can be made. This crosshead weighs 158 lbs. and has been successfully used in passenger engines built by the Schenectady Locomotive Works, and which have 19-in. cylinders, boiler pressure 190 lbs.

It consists of one steel casting, and the wings and wrist pin are hollow. The wearing surfaces are faced with cast iron gibs, with bosses fitted accurately by templates to the body of the crosshead, and held by brass rivets. The very light and strong crosshead shown in Fig. 14 is used by the Pennsylvania Railroad in their Class "L" high-speed locomotives; cylinders 18½ ins. diameter, boiler pressure 185 lbs. It weighs 146 lbs., and is used in connection with a single cast-iron box or enclosed guide. The wearing surfaces of the crosshead are lined with tin about ⅛-in. thick. As these surfaces are very large and well protected from dust and cinders, the wear is slight. The pin can be removed when necessary for trueing up or to disconnect for any purpose. This also permits of the use of the connecting rods with solid front ends, or without straps and bolts, thus further reducing the reciprocating weights.

Fig. 15 shows a cast steel crosshead weighing 150 lbs., used by the Norfolk & Western Railroad in its Class "D" engines, cylinders 19 ins. diameter, steam pressure 150 lbs. It is for four-bar guides, and the wearing surfaces are faced with white metal. The wings are cored out to lighten them. This crosshead, though light, seems to be of ample strength for the work required, and could perhaps be made still lighter.

For freight engines a very good design of the Laird type is shown in Fig. 16. It is made by the Rogers Locomotive Company. It weighs 198 lbs., and is designed for 20-in. cylinders and boiler pressure of 175 lbs. The body is a steel casting with a cast-iron block for wearing surfaces on guides. Referring to this type of crosshead, the superintendent, Mr. Wells, says:

"We do not advocate the Laird type for engines that make anything like high speeds, for the reason that the center of gravity of the crosshead is too far above the

center of the rod (it is out of balance), but for slow or moderate speeds it seems to give good results in practice.'

The crosshead shown in Fig. 17 is used by the Pennsylvania Railroad in their new type of mogul heavy locomotive for fast freight. The compound locomotives of this type carry 205 lbs. pressure, and the simple 180 lbs. The cylinders of the former are 20 ins. and 30 ins. diameter, and of the latter 19 ins. diameter. The crosshead is all cast steel and weighs 296 lbs. The bearing surfaces are all lined with block tin. The shoes are drilled with jigs, and other shoes can be quickly substituted when necessary to retire them.

This crosshead is a very good example of what can be done by the substitution of steel for iron, the comparison of the design with the Class "R," having same type crosshead, but made of wrought and cast iron, and which is given in Table I., gives a reduction in weight of 108 lbs., with a difference of 14,141 lbs. total piston pressure in favor of the Class "R."

Main Rods.

In main rods, as now used on locomotives for very high speeds, and which are subject to the stresses due to the up-and-down motion at 400 or more revolutions per minute, it has been found necessary to place the metal where it would be most effective. This is undoubtedly the I section, with broad top and bottom, and substituting steel for iron, the allowable stresses are somewhat greater, and the web and flanges can be made thin, which has the effect of considerably reducing the weight. Your committee believe that main rods of steel and of properly designed I section, and of solid front ends, will provide about as much reduction in reciprocating weight as can be had from this source.

An excellent example of this type of main rod is shown by Fig. 18, and which is used in the Class "L" locomotive of the Pennsylvania Railroad.

The drawings accompanying the report, and which illustrate the Pennsylvania Railroad practice, have been furnished your committee by Mr. F. D. Casanave, general superintendent of motive power, who also sends in addition the accompanying table, which gives a comparison of the weight of reciprocating parts for the Class "P" 18½-in. cylinders, 160 lbs. pressure, and the Class "L" 18½-in. cylinders, 185 lbs. pressure, parts of which are shown in Figs. 14, 18 and 19. Also a comparison between their Class "R" consolidation freight engine, 20-in. cylinder, 140 lbs. pressure; and the mogul freight engine, 19-in. cylinder, 205 lbs. pressure, Figs. 17, 18 and 19. It will be seen that, notwithstanding there is a very decided increase in piston pressure of the Class "L" over the Class "P," and in the mogul over the Class "I," in both cases there is a large reduction in the reciprocating weight.

Comparison of Weights of Reciprocating Parts, P. R. R. Locomotives.

Class of engine.	"P."	"L."	"R."	Mogul.
Main rod, front end....	144½	121	171	104½
Crosshead, complete.. .	174	146	277	269
Piston and rod, complete.	310	269½	368	324
Total reciprocating wt.	628½	536½	816	697½
Total piston pressure..	43,008	49,729	43,982	58,123
Piston pressure per lb. of reciprocating wt.....	68.4	92.7	53.9	83.3

Your committee has endeavored to give some of the lines that can be safely followed in reducing the weight of reciprocating parts, and it may be said that in all the designs, drawings of which are shown, the expense of production, and possibly of repairs, are considerably greater than with the heavier designs made largely for cast and wrought iron, but it must be borne in mind that these designs were adopted principally because of their low first cost and cheapness of maintenance, and the question of weight was considered of secondary importance, and your committee has not been able to learn of any method of design or construction that has yet been brought out by means of which the weight of reciprocating parts can be very materially reduced without entailing considerable increased cost over former methods of construction.

H. D. Gordon, C. F. Thomas, C. G. Turner, T. A. Lawes, John A. Hill, Committee.

◆

THE LINK MOVEMENT ENGINE.

The accompanying diagrams illustrate a curious mechanical movement adopted in a steam engine, which was recently described in "The Engineer" (London). The engine is patented by Mr. G. Chapman and was constructed by Messrs. John Milne & Son, of Edinburgh. The object of the inventor is to dispense with connecting rods, and thus to produce a very compact engine. The engine has two cylinders placed at right angles with each other, each cylinder in the actual engine being inclined 45° from the vertical, instead of one being vertical and the other horizontal, as in the diagrams. "The Engineer" describes the engine as follows:

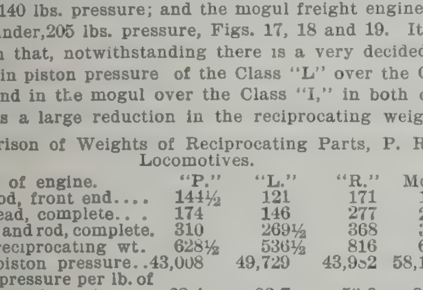

Fig. 1 and Fig. 2.--Diagrams of the Motions of Chapman's Link Movement Engine.
Built by John Milne & Son, Edinburgh.

> Roughly speaking, the two pistons move diagonally, and cross and recross midway at every stroke, a link, half the length of each, connecting them; a pin at each end of the link passing through the crossheads forms the respective cranks, and circular motions cause the rotation of the shafts, the pressure on the slippers being reduced to a minimum.
>
> It is a known geometrical fact that any point in the circumference of a circle revolving on the inside of another of double the diameter will describe a straight line. Mr. Chapman's engine utilizes this principle in a way that will be readily understood by the aid of the two small diagrams annexed. Fig. 1 shows the pistons at the ends of their strokes, and Fig. 2 shows one at half stroke. The crank length is from A to B, or half the diameter of the virtual circle within which the crank pins revolve. Any of our readers accustomed to geometrical work will see that this is an extremely pretty parallel motion without further description. The details of the engine have been very neatly worked out. It is not possible to dispense with guides, because the pressure on the piston varies. But Messrs. Milne say that a new engine which they have tested gave about 78% of its indicated power on the brake at 180 revs. per minute. This, for a small engine, with cylinders only 5 in. diameter by 10 in. stroke, is very good work.
>
> The cranks are side by side, the flying crank C, Fig. 2, acting like an ordinary drag link. This seems to us to be a very meritorious attempt to solve a difficult problem.

◆

THE ADVANTAGES OF RIBBED GLASS AND OF WIRE GLASS.

Some very interesting experiments were carried out some time ago for the Boston Manufacturers' Mutual Fire Insurance Co., which showed that ribbed glass gave far better illumination in a room than ordinary smooth glass. The tests were made by Prof. Chas. L. Norton, of the Massachusetts Institute of Technology, and the following was his report:

> The glass experimented upon was furnished by the Boston Plate and Window Glass Co. It included ribbed or fluted glass of four grades. No. 1 was 3-16-in. thick and had four ribs to the inch; No. 2 was ⅛-in. thick and had 11 ribs to the inch; No. 3 was ⅛-in. thick and had 21 ribs to the inch, and was of a strong greenish tint; No. 4 was same as No. 3, but was nearly colorless; No. 5 was ⅛-in. thick rough plate; No. 6 was ⅛-in. thick white cathedral; No. 7 was ⅛-in. thick white endoyance; No. 8 was single-thick ground glass; No. 9 was yellow tinted plain glass.
>
> Photometric comparisons of the intensity of the light from two windows similarly situated, one glazed with plain glass and the other with ribbed glass, show a difference of from 50 to 200% in favor of ribbed glass. The ribbed glass, No. 4, the best of those tested, transmitted, with ribs horizontal, in a direction perpendicular to its plane, 2.9 as much as plain glass, and in a direction 30° to the right and left, 2.5 times as much as plain glass, and in a direction 60° to the right or left, 1.9 times as much light as plain glass.
>
> It may be well at this point to describe briefly the distribution of light in a room when illuminated through ordinary window glass. In both fair and cloudy weather the general resultant direction of the light entering through a window is downward, ordinarily at an angle of 40° or 50°. The brightest portion of the room is therefore the floor in front of the window. As a floor is not, as a rule, a good reflecting surface, a large amount of light is absorbed there and lost. Such light as is reflected goes upward and backward toward the ceiling. Such light as falls on the wall spaces between the windows must therefore be mainly light which is diffusely reflected from the floor and objects upon it. Early in the morning and toward evening the angle of the incident light with the horizontal is less, and the light therefore penetrates further into the room, but the wall spaces between windows gain but little by this greater obliquity.
>
> If panes of ribbed glass be substituted for the plain glass the bright spot on the floor in front of the window disappears, and the entire floor, walls, and ceiling appear of sensibly the same brilliancy. The action of the ribbed glass appears to be prismatic, the greater part of the light falling on the ribbed glass at any point being refracted and spread out into a fan-shaped beam lying in a plane nearly perpendicular to the plane of the glass and to the direction of the ribs. This being recognized as the probable action, photometric measurements of the intensity were made at a distance of 8 ft. back of the glass in a horizontal plane, at five angles in this plane.
>
> Two panes of glass whose relative merits were to be compared, were set one above the other in a large window having a southern exposure. On the inside, with the panes for centers, were built two rooms, semicircular in plan, and each about 3 ft. high and 8 ft. radius. Outside the rooms was a photometer room entirely enclosing both. The panes were 18 ins. square. At corresponding points in the two rooms holes were cut in the side walls and disks of semi-transparent membrane, ground glass or paper were placed over the holes. One hole was directly opposite the pane and the others were at 30 and 60° to the right and left. The holes in the lower room were directly under those in the upper room, and by means of a system of mirrors any two corresponding disks could be viewed side by side. If one disk was brighter than the other, the corresponding pane was obscured by a shutter sliding across it until the disks appeared equally bright. The amount of light falling upon the two disks now being the same, the amount transmitted per unit of area of the glass is inversely as the area exposed.
>
> It must be distinctly understood that I do not mean that this gives the amount of light actually passing through the glass, but simply the amount which passes through in such a manner as to be available at the disks. Thus, if half of the ribbed glass pane has to be obscured in order to equally illuminate two corresponding disks, the ribbed glass is transmitting to the disk twice as much light per square inch as is the plain glass, and hence of two equal windows the ribbed glass window would give to objects situated in the general direction now occupied by the disk twice as much light as the plain glass window.
>
> None of the other samples gave such efficiency as did the ribbed glasses, the fine-ribbed, No. 4, being the best. It was found that the effect of having the ribs horizontal was to give an increase of light at the middle hole, and a less increase at the sides. Whereas the vertical ribs gave a greater increase at the sides and a less increase at the middle. The horizontal ribs tend to throw the light which would otherwise fall to the floor straight ahead far into the room, while the vertical ribs spread out the light on both sides. It is, however, useless to discuss the measurements of the distribution with horizontal ribs, as the brilliancy of the glass itself is then so great as to be unbearable, rendering its use in this position out of the question, for most purposes.
>
> The diffusion of heat was much the same as the diffusion of light. There was no spot where the heat rays from outside streamed directly in when ribbed glass was used, and objects near the window were cooler than when plain glass was used by from 4 to 15° F. However, the ribbed glass itself is hotter than the plain glass and the temperature of the air in the two cases was not sensibly different.

The company has also just published views showing the results of tests on the fire-resisting qualities of wire glass. The tests were made by the Secretary and Inspector of the Philadelphia Fire Underwriters' Association, April 30, 1896.

A brick test house was built 3 × 4 ft. inside and 9 ft. high. Iron grate bars were placed at the bottom of the house and openings left on the side walls near the ground for purposes of draft. This structure was piled for two-thirds of its height with wood treated with a liberal allowance of oil and resin. The skylight was glazed on one side with ¼-in. wired glass, on the other with ¼-in. rough glass without wire. In five minutes after the fire had been lighted the latter had broken and fallen in. The fire was maintained for forty minutes, and at the end water from a hose was played on the glass.

The wired glass in the side of the building, not being well attached by iron clamps was bent out of shape without giving way or yielding. The plate in the door was unimpaired, being set in a wooden frame fully encased in tin.

The results of this test are corroborated by a fire in the works of a stamping company at Newark, N. J., practically destroying the works. The buildings had several wire glass windows in place of iron shutters, and these withstood the heat successfully without rupture.

◆

THE DETROIT MUNICIPAL STREET ELECTRIC LIGHTING PLANT.

The municipal electric lighting plant at Detroit has now been in operation for nearly a year. The Public Lighting Commission has just issued its first annual report, covering the construction of the plant and its operation up to June 30, 1896. The specifications for the plant and the bids for its construction were published in our issue of March 1, 1894, and the Peck boilers were illustrated and described in Engineering News for June 20, 1895. The following information is abstracted from the report:

Prior to the establishment of the municipal service, the city was lighted by contract; Detroit being one of the first cities of the country to be lighted by electricity. The contract was held by the Brush Electric Light Co., from 1884 to 1890, inclusive, and from 1891 to 1895 the Detroit Electric Light & Power Co. supplied light, but the city plant was put in partial operation in April, 1895. The number of lamps furnished each year, the total amount paid the companies for street lighting, and the cost per lamp, from 1884 to 1894, inclusive, was as follows:

Year.	Total No.	Paid to companies.	Av. per lamp.
1884	24	$3,650	$152
1885	300	71,982	240
1886	382	91,571	240
1887	565	115,490	204
1888	608	117,370	193
1889	702	128,063	182
1890	719	137,937	192
1891	1,031	133,717	130
1892	1,168	152,283	130
1893	1,279	164,831	129
1894	1,279	169,360	132

The agitation for municipal ownership began with the first annual message of Mr. H. S. Pingree, Mayor, in 1890. The subject was urged in succeeding messages for 1891, 1892 and 1893, and in March of the latter year authority was secured by the city to establish a public lighting plant. In April the people voted in favor of such a course, 15,282 to 1,245. Early in the year bids were invited for lighting the city for varying periods, from one to ten years. Only one company bid, the one then lighting the city, its figures ranging from $154 per lamp per year for a one-year contract to $102 for ten years. The city had no power to contract for more than three years; the offer for such a period was $124 a year.

The plant was constructed by a commission of six members, appointed by the Mayor and confirmed by the Council. Mr. Alex. Dow, M. Am. Inst. Elec. E., was chief engineer or city electrician, from June 14, 1893, to July 1, 1896, when he resigned and was succeeded by Mr. Walter D. Steele, who had been assistant city electrician since June 3, 1895. Mr. Jesse M. Smith, M. Am. Inst. Elec. E., and Prof. H. S. Carhart, Assoc. M. Am. Inst. Elec. E., were consulting engineers. Mr. Will F. Conant was secretary of the public lighting commission up to July 1, 1896, when he was appointed secretary and general manager.

The central station is located on the river front, where 64,175 sq. ft. of land has been devoted to the purpose. Next to the street, the station consists of a brick office building three stories high, 136 ft. front, 35 ft. deep at one end and 14 ft. deep at the other. The first floor is divided into shops and storerooms; the second is used for offices by the commission, and the third for bulky stores. A 16-ft. alley separates the office building from the power house. The latter includes a 50 × 150-ft. engine and dynamo building, 48 × 150-ft. boiler house, the two being joined by a building 17½ ft. wide, containing accommodations for the engineer, bath rooms, lockers and other rooms. A dock and railway siding give facilities for receiving supplies. The site cost $63,125, and the building, $72,248.

The steam plant includes seven Peck double deck, tubular boilers, fully described in our issue of June 20, 1895, and five triple expansion condensing engines, built by S. F. Hodge & Co. The engines have been found to give the best economy when indicating from 250 to 340 HP. each.

The electric generating plant includes 18 50-K-W. dynamos for series arc lighting, furnished by the Western Electric Co. and three 55-K-W. alternating current dynamos of the two-phase type, furnished by the Westinghouse Electric & Manufacturing Co. for the 2,500 incandescent lights required in 14 public buildings.

The distribution is divided into two sections, the first being an underground system within a one-half mile radius of the city hall and the second overhead construction. The main lines of the underground system are vitrified clay tile laid in concrete, with laterals of 2½-in. wrought iron dipped in graphite paint. The tile conduits have from 4 to 24 ducts and aggregate 181,794 ft. of single duct, costing an average of 23¾ cts., complete, including 88 manholes connected with the public sewers. The total mileage of main line, or tile conduit, is 34.43, and of lateral, or iron, 6.3 miles, the latter costing 34¾ cts. per ft., including 149 manholes. Of the 40.73 miles of underground conduits only 12.7 miles are yet occupied with public lighting wires, the balance being available for extensions, or for rental. At present 2,503 incandescent and 184 arc lamps are supplied through the underground system and 1,309 on the overhead system, the arc lamps being of 2,000 c. p. The underground cables are rubber insulated, with tape and lead covering the rubber. The arc circuit cables have 7-32 ins. of rubber around a No. 4 copper conductor. The feeder cables for the incandescent system are the same as those just described and the mains have 9-64 ins. of rubber around a No. 8 copper conductor. These cables were furnished by the Safety Insulated Wire & Cable Co., of New York. The underground work cost $87,602; the pole and wire system, $107,780; and the 135 lamp towers $85,099.

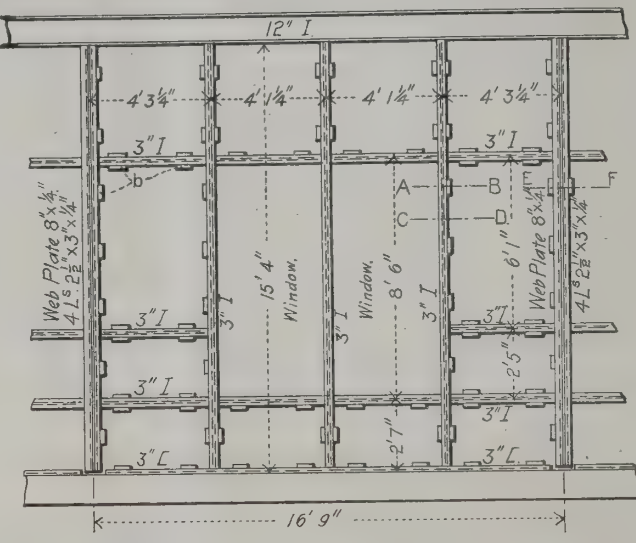

Fig. 1.—Iron Frame at Barclay Street Ferry House Ready to Receive Filling of Rock Plaster

The poles for the 1,309 arc lamp on the overhead system, so far as set by the commission, range from 40 to 70 ft. in height; up to 55 ft. they are cedar and the 220 above that height are of Norway pine. There are 329 miles of wire. The number of poles set by the commission is 4,378, public lighting wires being placed on 1,435 police and fire department poles, up to the end of 1895, and the wires of these departments being placed on 797 lighting poles. An interchange of the use of poles has also been effected with some of the private companies which use the streets.

About half of the lamps are supported by one-light cranes; 500 are supported on 135 towers, 45 of which have three lights, 87 have four, one has 5 and two have 6. Of the 135 towers 23 are within the half-mile radius and most of the remainder are in the outer districts where the buildings are small and scattered and the foliage is not dense. Eight of the towers are 100 ft. high; two are 175 ft., and the balance are 150 ft. high. The hours for lighting are from one-half hour after sunset to one-half hour before sunrise every night in the year. The police department reports all lamps not burning, as it did when the city was lighted by contract.

The report contains two tables, one relating to lamps out during nine months of contract operation, of 1,279 lamps, and the other to city operation of 1,483 lamps. According to these figures the percentage of hours out under contract ranged by months from 0.834% in January to 3.867% in December, and under city operation from 0.42% in June, 1896, to 0.201% in October, 1895.

Since Oct. 1, 1895, the entire city has been lighted by the public plant, the number of lamps on Oct. 1 having been 1,470, and on June 30, 1,492, the average number of lamps in service being 1,483.

The cost of running the plant during the nine months named was $82,803. This was divided as follows:

Coal at $2.19 per ton	$12,208
Labor and management	55,822
Carbons	5,820
Oil and rags	1,150
Teaming	1,970
Globes and nets	476
General supplies	4,472
Printing and stationery	237
Freight and transportation	126
Incandescent lamps	328
Surgeon and hospital	194
Total	$82,803

Deducting $6,606 for the cost of operating the incandescent lamps, leaves $76,197, or $68.52 per lamp per year, for the average number of arc lamps lighted during the period. To this the report adds $16.18 per lamp for interest on bonds, making $84.70 per lamp per year, against $133.80, which the city was paying before its plant went into operation. It should be remembered, however, that the city had an offer of $102 per year for a ten-year contract in 1893, or $124 for a three-year contract. While the city did not then have authority to enter into a contract for more than three years, neither did it at that time have power to build a municipal plant. Possibly authority to make a ten-year contract could have been secured from the legislature, had that been deemed advisable, fully as easily as power to establish a municipal plant. But even taking $102 as the cost per lamp and allowing 2½% for a sinking fund, the municipal plant would give cheaper service, according to the figures in the report, than would have been obtained under a ten-year contract.

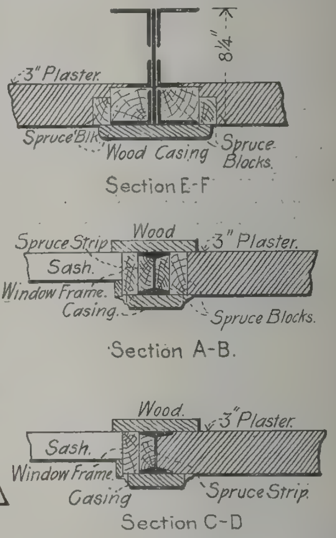

Fig. 2.—Sections Through Wall of Barclay Street Ferry House After Plaster Panels are Built in

The city now has the advantage, also, of quite an extensive underground conduit system, which of course increases capital charges, especially just at present, when less than a third of it is in use, but which later on may perhaps be a source of considerable revenue.

The total cost of the lighting plant up to July 1, 1896, was $641,247, less $11,106 of credit for labor and material, or a net amount of $630,142. This includes no allowance for interest during construction. About $600,000 of the cost was realized from the sale of bonds.

◆

A NEW METHOD OF FIREPROOFING.

The Barclay St. ferry house, owned by the Hoboken Ferry Co., of New York city, which has just been open to the public, presents quite a new departure in fireproof construction. The aim has been to make a wall or partition which would not furnish combustible material for a fire and yet would be suitable for a structure built on a dock and subject to the vibration caused by the impact of heavily loaded ferry boats. Only those partitions which enclose portions of the building which are to be heated in winter are constructed in the manner described.

The design is by Mr. Alexander Stevens, 99 Cedar St., New York city. The steel frame work was made as rigid as possible; no bolts were used, but every connection was well riveted. The studding consists of 3-in. I-beams, weighing 5½ lbs. per ft. These vertical studs are connected at intervals by similar horizontal beams; these latter are of the same size and weight as the vertical ones and have their flanges lying in the same planes. This made a rectangular opening with a groove extending around the inside of its perimeter, formed by the flanges of the beams, the bed of the groove being the webs, Figs. 1 and 2.

After the iron frame was in position, nailing blocks, b, b, b, Fig. 1, were fastened between the flanges of the I-beams by screws through the webs. These blocks were cut of sufficient width

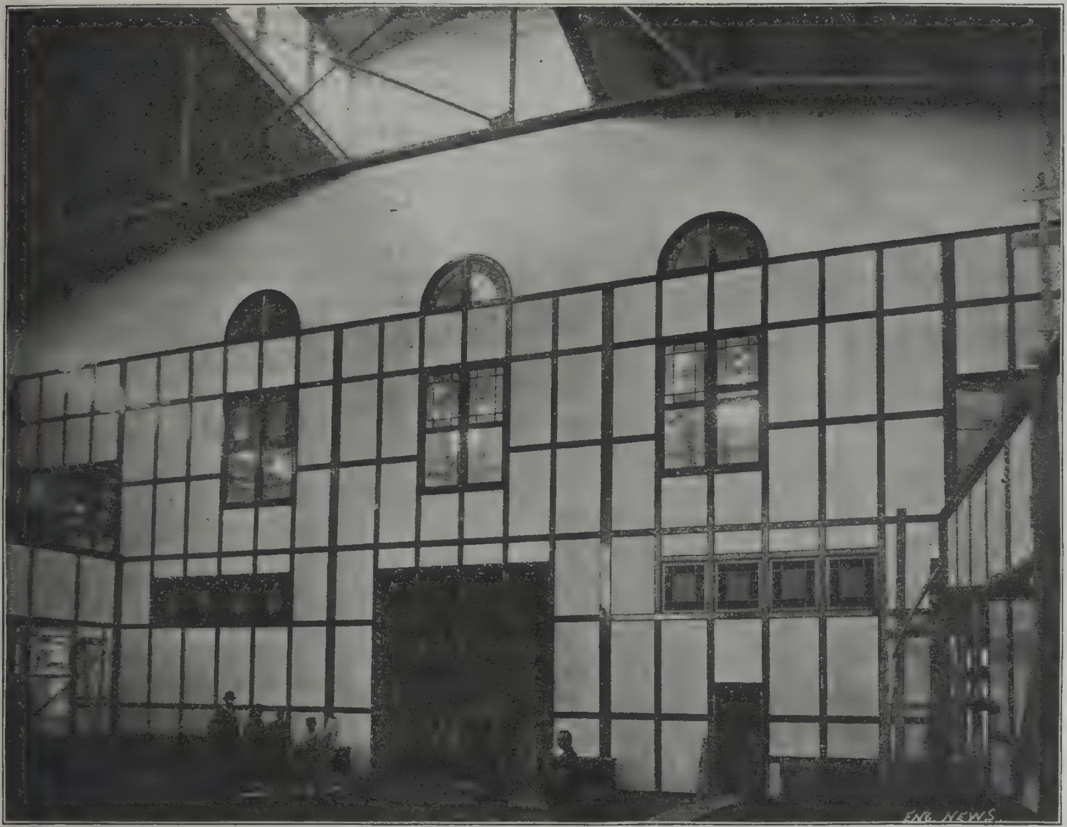

FIG. 4.—FINISHED WALL AT BARCLAY STREET FERRY HOUSE.

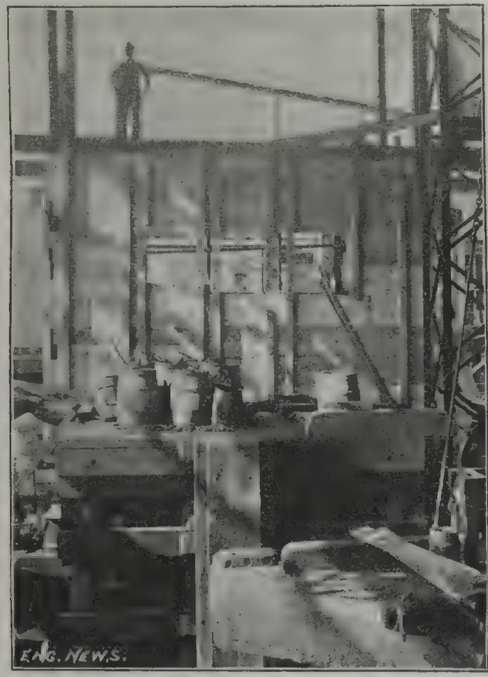

Fig. 3.—Molds in Position for Grouting in Plaster.

to come flush with the flanges on either side. The frame was now ready for the fireproofing. This is a hard plaster, made by the Rock Plaster Co., of Hoboken, N. J., and consisting primarily of lime, plaster of paris and sand, with an admixture of hair. The net work of iron I-beams, Fig. 1, composing the frame work for the walls and partitions was boarded up on both sides with 2-in. spruce lumber. These boards were held in position by verticals through which iron bolts were passed about every 4 ft. An opening from 3 to 6 ins. in width was left on one side of the wall just below the flange of each horizontal beam. Into these openings, plaster was poured as a grout and settled down into the mold formed by the plank siding and the beam flanges. The work of filling the molds was done by ordinary laborers. The photograph (Fig. 3) shows one of these molds in position, the openings for pouring in the plaster being on the opposite side. To fill the top portion of the rectangular space the plaster was mixed with sufficient water to make a stiff mortar and was crowded into place with a trowel. A mason had to be employed for this part of the work, experiments with common laborers failing to give good results. The molding boards were removed in a few hours. After their removal the surface of the plaster was flush with the surfaces of the flanges of the I-beams, which showed as a series of broad rectangular lines in the mortar wall with here and there the nailing blocks. On the inside of the building, where a smooth finish was desired, the work was finished off with a coat of "Rock White." Finishing strips of mahogany lumber were then put on over the lines of the beams, Fig. 4. On the outside the finishing coat was made of plaster itself, troweled hard, and about ¾-in. thick. The outside was then washed over two or three times with a solution of sulphate of zinc in order to convert any free lime near the surface into sulphate of lime and so make the wall more impervious to the weather. Though very hard, the plaster is somewhat affected when entirely exposed to the weather. The action of the weather on such a wall is very much like the rusting of iron; a scale forms which flakes off, but the portion underneath is not affected. For this reason, if it is kept properly painted, it should last as long as the piles supporting the building. The plaster is much harder than ordinary lime plaster, but it is claimed to be more elastic and less easily fractured by the motion which it is impossible to avoid in a ferry house built on piles. Some of the plaster at the Barclay St. ferry house has been in place for a number of months and is now about as hard as it ever will become. It shows no tendency to crack and appears to fulfill all of the requirements. The cost of the plaster, including the finishing coat on both sides, was 46 cts. per sq. ft.

◆

LEGAL DECISIONS OF INTEREST TO ENGINEERS.

Validity of Law Compelling Corporation to Assign Reasons for Discharge of Employee.

The public, whether as many or one, whether as a multitude or a sovereignty, has no interest to be protected or promoted by a correspondence between discharged agents or employees and their late employers, designed, not for public, but for private information as to the reasons for discharges, and as to the import and authorship of all complaints or communications which produced or suggested them. A statute which undertakes to make it the duty of incorporated railway, express, and telegraph companies to engage in correspondence of this sort with their discharged agents and employees, and which subjects them in each case to a heavy forfeiture, under the name of damages, for failing or refusing to do so, is violative of the general private right of silence enjoyed by all persons, natural or artificial, from time immemorial, and is utterly void and of no effect. Liberty of speech and of writing is secured by the constitution, and incident thereto is the correlative liberty of silence not less important nor less sacred. Statements or communications, oral or written, wanted for private information, cannot be coerced by mere legislative mandate at the will of one of the parties and against the will of the other. Compulsory private discovery, even from corporations, enforced, not by suit or action, but by statutory terror, is not allowable where rights are under the guardianship of due process of law. It follows from the foregoing that the act of October 21, 1891, entitled "An act to require certain corporations to give to their discharged employees or agents the causes of their removal or discharge, when discharged or removed," is unconstitutional, and that an action founded thereon for the recovery of $5,000 as penalty or arbitrary damages fixed by the statutes for non-compliance with its mandate cannot be supported.—Wallace v. Georgia, C. & N. Ry. Co. (Supr. Ct. of Ga.), 22 S. E. Rep. 579

Condemnation Proceedings.

The only right of a city to condemn certain property being based on the necessity of acquiring it in order to carry out its contract to provide a railway company with terminal facilities, the fulfillment of that contract operated to extinguish any easement which the city might have acquired in the property along the right of way. Such power being primarily lodged in the state, and which may from time to time be granted to other corporate bodies, as to cities, for municipal purposes and to railway companies engaged in the public service as common carriers, and others, but always for some public use. Of this public use the state is usually the recognized judge, and her action in declaring a public use is seldom questioned by the courts. Incident to this power, however, always accompanying it, and as a constant and wholesome restraint upon it, are these two questions of fact: First, whether the property sought to be taken is really and in fact necessary for the public use; and, second, the question of just compensation, these two questions always being subject to the determination of a jury, and to be approved by the court.—Dennis Long & Co. v. City of Louisville (Ct. of App. of Ky.), 32 S. W. Rep. 272.

Liability for Defect in Street.

When a street railway company obtains a franchise from the city, agreeing to keep its tracks at proper grade, and an accident happens through its failure to do so, for which the city is liable in damages, the company is liable over to the city.—City of Fort Worth v. Allen. (Ct. of Civ. App. of Tex.) 31 S. W. Rep. 235.

Ancient Maps and Deeds.

In a suit for the recovery of real estate, a map purporting to describe, among others, the tracts in dispute, was offered in evidence. The map was not dated or signed by the surveyor who made it, but from field notes and other evidences it was shown to have been made in 1818, by a well-known and skillful surveyor, long since dead. Other surveyors testified that they had used and tested the map in their own surveys, and that it was the earliest known survey of the district it purported to describe. It also appeared that it related to an actual transaction, having been made to show the abutting owners along a proposed new road. The court held that it was admissible as an ancient map.—Whitman v. Shaw (Sup. Jud. Ct. Mass.) 44 Northeastern Rep., 333.

Special Assessments and Railroad Right of Way.

The right of way owned by a railroad may be assessed for improvements of a street on which it abuts; and in an action brought under a statute in which the contractor seeks to recover such assessment a personal judgment may be rendered against a company.—P., C., C. & St. L. Ry. Co. v. Hays (App. Ct. Ind.) 44 Northeastern Rep., 375.

Agreement of Abutting Owner to Pay His Share.

An abutting owner who agrees with one having a contract with the city to improve a street to pay his share of the cost of improving the street is personally liable for such amount, if the improvement is completed in accordance with the contract.—Burton v. Laing (Ct. Civ. App. Tex.) 36 Southwestern Rep., 298.

Stream Used as Sewer.

Where a municipality adopts and uses a stream as an open sewer, and fails to keep its channel open and to remove accumulations which obstruct the flow of water and throw it out of its banks up on the adjoining land. the land owner has the right of action for such injury, although the stream had been used as a sewer for 30 years.—Blizzard v. Danville (Sup. Ct. Penna.) 34 Atl. Rep., 846.

When Violence is Not an Excuse for Failing to Run Street Cars.

A street car company cannot excuse a failure to run its cars on the ground that it has been prevented by violence from doing so, where it does not appear that the civil authorities have failed to protect it fully in its efforts to operate its road. The fact that such company cannot get employees to accept its terms gives it no right to stop running its cars.—Loader v. Atlantic Ave. Ry. Co. (Supr. Ct. of Kings County, N. Y.) 35 N. Y. S. Rep., 999.

Conclusiveness of Estimates by Engineer.

A provision in a contract for railroad construction work that the payments therefor shall be made according to the estimates of the engineer of the railroad company, and that the final estimate of the engineer as to the quantity of the work, etc., shall be conclusive between the parties, without further recourse to appeal, does not prevent the estimates from being attacked for mistake or fraud, but merely makes them prima facie correct, as parties cannot agree in advance to oust the jurisdiction of the courts. Such fraud or mistake need also only be shown by a preponderance of the evidence.—Baltimore & O. & C. Ry. Co. v. Scholes (App. Ct. of Ind.) 43 N. E. Rep., 156.

As to the Number of Street Cars that Must be Run.

The number of cars to be run by a street car company is a matter within the discretion of the board of directors, subject to the power of the courts to compel them by mandamus to increase the number, whenever public convenience may require it.—Loeder v. Brooklyn Heights Ry. Co., 35 N. Y. S. Rep., 996.

ENGINEERING NEWS

AND

AMERICAN RAILWAY JOURNAL.

Published every Thursday at Tribune Building, New York.
Entered at the Post Office, New York, as Second Class Matter.

LONDON AGENCIES: KEGAN PAUL, TRENCH, TRUEBNER & CO. (Limited), Paternoster House, Charing Cross Road; SAMPSON LOW, MARSTON & CO., (Limited), St. Dunstan's House, Fetter Lane.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32d *week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The publication of the results of the Louisville water purification experiments, which terminated on July 1, as noted in another column, will be awaited with the greatest interest by a large number of engineers and sanitarians. Seldom have there been scientific experiments of so long duration conducted in a manner which promises such valuable results. The Lawrence experiments on slow sand filtration, as a means of removing bacteria from water and reducing its contents in organic matter, are of course unexcelled, but they have been conducted with small filters and have no relation to mechanical filtration and but little bearing on the problem confronting those who have to deal with the silt-bearing waters of the South and West. The Louisville experiments have been carried out in a thoroughly practical manner and with plants in every way comparable in size and modes of operation with those in actual service. The unit tank for a mechanical filtering plant very commonly has a daily capacity of 250,000 gallons, which was the size of those used in the experiments, so that larger plants would be a mere multiplication of tanks, with practically no changes in modes of operation. Further than this, the experiments have been planned and carried out under the direction of Mr. Chas. Hermony, M. Am. Soc. C. E., for many years chief engineer of the Louisville water-works, with Mr. Geo. W. Fuller, formerly of the Lawrence Experiment Station, as chemist and bacteriologist in charge, and with an ample staff of able assistants. The competing companies have had able men in charge of their plants, so that everything has been favorable to the securing of valuable results.

Expensive as these experiments doubtless have been for both the city of Louisville and the competing companies, it seems certain that the money has been well spent. The city might have wasted large sums year after year, on an improperly designed plant, had it gone ahead without the experiments, and the impartial data secured regarding their processes cannot but be of value to the companies.

◆

Lack of space and time prevented us from commenting last week upon the very interesting tests of the resistance of loaded metal columns to heat which were recorded in our last issue. We advise any of our readers who may not already have done so to bestow careful study on these tests, as they appear to us about the most valuable that have ever been put on record. It will be noticed that the tests were made on full-size columns; that loads were applied well up to what would be used in actual practice, and that the columns were subjected to temperatures which must have equaled those which are reached in any but very severe conflagrations.

Turning now to the results of the tests, the surprising thing to us is that the columns stood up under their load so remarkably well. The committee which made the test is non-committal as to what it thinks or does not think as to the lessons to be drawn from the tests; but it will be noted that the load which they applied to the columns equaled the full capacity of their hydraulic press. We imagine that if they were rebuilding their testing plant they would instal a larger press.

A great deal has been said and written about the necessity for thoroughly protecting iron work by fireproofing, and we would by no means lessen the force of this; but every engineer who realizes the fragile nature of most fireproofing materials will be very glad, we are sure, to learn that a bare steel or cast-iron column can stand unharmed in a temperature of 1,000 to 1,200°, even though it is under a very considerable load, and further, that a good deal of abuse in the way of hose streams turned on when it is at a red heat is required to do it serious harm.

But in this connection many of our readers may recall a photograph published in our issue of July 2, showing the ruins of a steel frame factory building of the Washburn & Moen Co. at Worcester, Mass., which was burned on April 5. Here was a building with almost no wood in its construction, and with very little inflammable material inside it. A tank of fish oil used for tempering springs was set on fire and the flames swept through the building almost instantly. In a very few minutes the structure collapsed a total wreck, almost every column being bent and twisted. We understand that the experience with this building is leading many engineers to advise against the steel frame for factory buildings, and go back to wood frames as after all the safest.

Now, the question comes, why did the columns in this Worcester building fail so suddenly and entirely, whereas those in the recent tests stood up so surprisingly well? We have considered this matter with some care and are able to find but one explanation: It will be noticed that the columns tested by the committee, which we showed last week, were all what may be called "hollow" columns. The columns in the Washburn & Moen shop, on the other hand, were made up of light steel plates (or channels) with light angles riveted to their edges. Thus the column depended for stiffness entirely upon light projecting flanges, which in a rush of flame are sure to be heated quickly, and are moreover likely to be heated unevenly on the two sides. May it not be that this class of column is more susceptible to the influence of heat than columns of hollow section? If this is actually the case, the fact would have an important bearing on the design of factory building. It is to be hoped that the able committee on tests of fireproofing may carry out tests on columns of this class and may also test the effect of heating columns on one side.

◆

The verdict of the coroner's jury on the Atlantic City accident is an excellent illustration of the difficulty of getting from a set of men who know nothing of a certain technical subject an opinion upon that subject that shall be of any value. While the jury recognized, as they could hardly fail to do, that Farr, the engineer of the Reading express, was negligent in failing to check the speed of his train in time, with the signals against him, they also held the towerman, Hauser, deserving of censure for giving the safety signal to the West Jersey train instead of to the express. Further, three of the six jurors, in an independent verdict, declared that the engineer of the excursion train erred in not exercising greater care in crossing ahead of the fast express.

The idea which governed the jurymen appeared to be that it was the business of every employee to take measures to prevent collisions at this crossing. It is fortunate, indeed, that such ideas have been abandoned in the operation of all railway lines of importance. The old idea was to make everybody alert to prevent accidents, in disregard of the well-known fact that what is everybody's business is nobody's business. The modern system is to give each employee certain fixed duties for which he, and he alone, is absolutely responsible, and in addition to make the matter of safety depend as little as possible on human memory and judgment, and as much as possible on mechanical safeguards.

As a matter of fact, neither the engineer of the West Jersey train nor the towerman deserve a single particle of blame in connection with this terrible wreck. The former obeyed the signals held up before him implicitly. It was no part of his duties to know anything about the trains on another railway which crossed his. Nor was it his duty to keep his train out of their way. It was of course his duty when the emergency came and he saw the Reading train coming down on the crossing at a speed too great to be checked to do anything possible to avert the catastrophe; but nothing was possible even to the wisest judgment or the coolest head in the few seconds before the crash came.

As for the towerman, if it was an error of judgment for him to give the slow excursion train the right of way over the crossing ahead of the express, it was an error of the most trifling character, and one which should have resulted in nothing more serious than a minute's delay to the express. The fact should be emphasized that the safety of the traveling public is not dependent upon the judgment of the towerman. If it were, then the howl of the newspapers about putting the lives of thousands of passengers at the mercy of a forty-dollar-a-month youth would be justified.

The great, prominent fact which the coroner's jury should have emphasized in its verdict, but did not, was that Farr, the engineer of the Reading express, used his judgment instead of obeying his orders, and made a fatal error of judgment when he approached the distant signal at so high a speed that he was not "prepared to stop at the home signal," as the rules required. The towerman obeyed orders; it was his duty to give the right of way to whichever train he deemed best. The engineer of the excursion train obeyed orders, for he had a clear signal for the crossing; but the engineer of the fast express did not obey orders, and on him the first responsibility for the catastrophe lies.

◆

We trust the Atlantic City accident will be studied diligently by those who have had the hardihood to claim that the running of very fast trains is attended by no more danger than the running of ordinary trains. While a few railway officers have made themselves prominent by defending this idea, it has been ably pointed out by others that the long distance required to stop a train running at a speed of 60 to 90 miles an hour, constitutes an element of danger that can never be wholly eliminated. The Atlantic City accident fully proves the correctness of this position. We do not imagine, of course, that train speeds are to be decreased, or that fewer very fast trains will be run in future; but their dangers will, we hope, be more fully recognized, and every means will be taken to instill into the minds of engineers that fixed signals must be approached with caution.

As we said last week, the Atlantic City accident will doubtless have an influence in checking the tendency to omit derailing switches at such especially dangerous points as grade crossings and drawbridges; but it ought also to show the necessity of still more strict training of enginemen to unvarying obedience to fixed signals. We cannot place a derail in front of every fixed signal, and at most places we must rely on the engineer's implicit obedience to the warning signal held up before his eyes.

◆

The New York Rapid Transit Commission has done wisely, we believe, in taking up anew the problem entrusted to it, and attempting to solve it on a more economical basis than was proposed in the original plan. Briefly, what is proposed is a four-track tunnel beneath the street surface from the City Hall to the Grand Central Station, with two-track extensions north, on the west side via Broadway and the Boulevard, and on the east side via Park Ave., adding a third track for express service where it is most needed. The limit of cost is set at $30,000,000; and there is every reason to believe that for this sum a system could be built which would serve the present need for rapid transit and which could easily be extended and enlarged later to suit the traffic requirements. We have always held that it was wise to save the five or ten million dollars which will be represented by the difference in the cost of building the road on Broadway or on Elm St., and that the road will draw practically as heavy a traffic on the one line as on the other. Should the road actually be constructed on Elm St., the Broadway shopkeepers and lot-owners who were chiefly instrumental in refusing it right of way on that street may eventually regret their action.

EXPORTING AMERICAN MANUFACTURES.

We do not recall a time when so much general interest has been felt by manufacturers everywhere in this country in the cultivation of an export trade as appears to be evident at present. At least three organizations, all of them of very recent formation, are now actively engaged in aiding manufacturers in the development of their foreign trade, viz., the Exporters' Association of America, with offices at Morris Building, New York city; the National Association of Manufacturers, with headquarters at 1757 North 4th St. Philadelphia, and the Philadelphia Museums, which occupy the old offices of the Pennsylvania R. R. Co., at 233 South 4th St., Philadelphia.

Each of these organizations appears to be carrying on a vigorous work and to be receiving the hearty support of the manufacturers, which it is designed to serve. The first named organization was briefly described on p. 33 of our issue of July 16. It is a purely voluntary association of manufacturers, and its chief functions appear to be to facilitate the export of goods by manufacturers who are not versed in the customs of foreign trade. To this end, the officers furnish to members reports of the financial standing of foreign customers and attend to consular and custom house work in connection with foreign shipments. Weekly reports of exports of goods in which each manufacturer is interested, are furnished to the members. The dues are $100 per year. Mr. Andrew H. Power is the Secretary.

The National Association of Manufacturers is a considerably more ambitious organization, which does not confine its activities entirely to foreign trade. It is interesting itself, for example, in the movement for a uniform freight classification and also the establishment of a Government Department of Commerce and Manufactures, a topic which we discussed editorially in our issue of April 23, 1896. But cultivation of foreign trade is, after all, its chief purpose; and in many respects it appears to cover a field very similar to that of the organization described above. In the last circular issued by this Association we find the following interesting statement:

> Suspicions of political purposes have done great injury to the association and have naturally retarded its progress: for there have been those outside of its membership who have not hesitated to raise the cry of politics upon every opportunity. The business motives and business methods of the association, however, have impressed themselves upon business men, and it is now pretty generally understood that the National Association of Manufacturers is essentially and wholly a business affair. The elimination of all elements of politics has given the association a membership of a representative character which would not be obtainable under the narrowing influence of partisanship.

Turning to the work of the Association, we learn that it has established a "Bureau of Publicity," at 1751 North 4th St., Philadelphia, where five persons are constantly employed. It took a prominent place in the agitation at the last session of Congress for bills relating to the restoration of treaties of commercial reciprocity, and the statement is made that "there is every prospect of favorable action during the next session." It organized a tour to South America by a party of leading manufacturers, which was noted in our issue of May 14. The party sailed on July 1, and will be absent until Sept. 1. It has also sent a committee of three to visit and report upon trade conditions in Mexico, a special Commissioner is now in Denmark, and another (Hon. Robert P. Porter) returned from Japan June 6 and will present a report to the Association on the industrial present and future of that country and its possibility of competition with American manufacturers. Preliminary steps have been taken toward the establishment of agencies for the exhibit of American manufactured goods abroad. A concession has been obtained from Venezuela for the establishment of warehouses at Caracas for the exhibit of American products, and similar concessions are proposed with other South American countries. The committee having this branch of work in charge includes Mr. John H. Converse, of the Baldwin Locomotive Works, Philadelphia, and Mr. Jas. M. Dodge, of the Link Belt Machinery Co.

The Philadelphia Museums is a concern on a quite different basis from the other two organizations described above. It appears to be aiming to aid the manufacturer in the purchase of his raw material, and the carrying on of his business quite as much as in the extension of his selling trade to foreign countries. It is practically a Philadelphia institution. The city councils chartered it June 15, 1894, and have thus far appropriated $120,000 for its expenses, of which $65,000 was appropriated this year. At present the museums are located in the building formerly used by the Pennsylvania R. R. Co. for its general offices, where floor space to the amount of 200,000 sq. ft. is available. A five years' lease of this property has been taken; but at the end of that time it is hoped that the institution will be housed in its own building. The city has already appropriated a building site of eight acres for the Museums (to which eight acres more are to be added), and appropriated this year $15,000 toward putting the site in condition for building upon.

The trustees of the museums are elected by the city councils and approved by the Mayor, and 14 already elected are to serve for life, the list including such names as Chas. H. Cramp, Thos. Dolan, Francis L. Potts, Wm. L. Singerly, Charlemagne Power, Jr., Frank Thomson and John Wanamaker. The Governor of Pennsylvania, the Mayor of Philadelphia and the President of each branch of the City Councils, are also members ex officio. There is also a "National Advisory Board" made up of "official delegates" appointed by various governments of foreign countries and the principal commercial organizations, such as Boards of Trade, Chambers of Commerce, Manufacturers' Associations, etc., of principal cities in the United States. This Advisory Board held its first annual meeting on June 24 and elected Henry W. Peabody, of Boston, President, and W. H. Parsons, of New York, Vice-President.

Turning now to the work which this institution is doing and proposes to do: It began its work by securing as the nucleus of its collection exhibits made by various foreign countries at the Columbian Exposition. These have been added to by gifts and purchases from abroad, and have been carefully arranged and classified. In 14 rooms on the first and second floors of its present quarters, the world's supply of raw materials are grouped. Thus all the cabinet woods are in one room, another has all the dyeing materials. In another series of rooms the classification is changed to a geographical one, and one set of rooms is devoted to Mexican products, another to Central American, etc. Still another series of rooms are devoted to exhibits of foreign manufactured articles, the idea being to show the American manufacturer with what goods he will compete in entering a foreign market. The collection in the museums now comprises over 60,000 objects, to which additions are constantly being made.

Finally there is a bureau of information containing files of over 500 trade journals, statistical publications, etc. The services which the museums will give to manufacturers are summarized as follows:

> The manufacturer who wishes to introduce his goods into new markets abroad will be shown samples of whatever is now salable in those markets. Full details as to the competition he may have to meet will be furnished him as follows:
>
> 1. Character and variety of goods demanded in various export markets.
> 2. The country from which imported, together with the names and addresses of foreign manufacturers, where possible.
> 3. The quantity imported annually into each particular city.
> 4. The manufacturers' price at the factory.
> 5. The retail prices in each city where sold.
> 6. Transportation charges from Europe to the various foreign ports compared with rates from the United States.
> 7. Import duties.
> 8 Character of packing.
> 9. The names and addresses of importers.
>
> This bureau will also collect detailed information concerning all public improvements in progress or contemplated in Spanish America, South Africa and other new export fields, which may be of interest to the commercial classes of the United States. The information and data of this bureau will be collected through American Consuls, foreign government officials, foreign merchants and the traveling representatives of the museum.
>
> The services of the museums, including this information, are free to all who come for it. The expense of copying, compiling and postage is asked of each manufacturer to whom the monthly reports are sent regularly. This has been estimated at $50 per year.

The Museums will not become a factor in the actual sale or introduction of American goods abroad, as this is left to such institutions as export commission houses, nor will it do the work of a commercial agency in reporting on the credit of foreign buyers. It will not advertise American goods, and American manufactures will not be displayed in the Museum. Prof. W. P. Wilson is the Director of the Museums, and Messrs. Gustave Niederlein and Wm. Harper are Chiefs of the Scientific Department and of the Bureau of Information, respectively.

We have described quite fully these several enterprises for the benefit of those of our readers who may be interested in the work that they have undertaken. Let us next inquire what significance lies in this general awakening of American manufacturers to the profit of cultivating an export trade. It was common enough a half-dozen years ago to hear manufacturers say that the home market was all they cared for. But the last three years have seen such an excess of productive capacity over current demand in the home market, that prices have been reduced to points never before reached. Manufacturers who ten years ago were selling all they could produce at good profits, are nowadays finding competition so sharp that prices are reduced to the lowest living figure, and in addition more money has to be spent in selling goods in order to hold customers and keep active competitors from securing them. It is entirely natural under these circumstances that the same men who a dozen years ago were chiefly concerned lest foreign competition should reduce their profits in the home market, are now in many cases fully convinced of their ability to hold this market against the competition of English or German or French manufacturers, and not only that, but to beat them in either price or quality in the markets of Asia, Africa and South America.

We are accustomed to hear so much of British competition, German competition, Belgian competition, Japanese competition, etc., with the products of American factories, that it is not strange that many people have obtained an idea that foreign manufacturing industries exceed those of this country in magnitude. But the fact is that the United States is by far the greatest manufacturing nation of the world. According to Mulhall the following was the total value of all the manufactured goods produced by the principal nations of the world in 1888:

United States	£1,443,000,000
Great Britain and Ireland	820 000,000
Germany	583,000,000
France	485,000,000
Russia	363,000,000
Austria	253,000,000
Italy	121,000,000
Belgium	102,000,000

It will be seen that according to these figures, in 1888 the manufactures of this country equaled in value the combined output of all the factories of Great Britain and Germany, which are, after the United States, the greatest manufacturing nations. In 1890, according to the United States census, the total value of the manufactured goods produced by the United States exceeded the above enormous total by nearly 30 per cent., the figure for the total being $9,056,765,000.

Now let us see how much of this total was exported. According to the last report of the U. S. Bureau of Statistics, the total value of all exports in the year ending June 30, 1895, was $807,638,000, of which about one-sixth was manufactured articles. Thus in round numbers the total value of our manufactured goods exported in that year was $135,000,000. What the exact total value of the output of our manufactories was during that year, there is no means of ascertaining; but we know that for two or three years after the census of 1890 was taken, the expansion of manufacturing industry in this country went on apace. Remembering that in the decade of 1880-1890, the product of United States manufactories doubled in value, it seems reasonable to believe that the fall in prices and the shrinkage in production that the past three years have seen, have not wholly offset the growth from 1890 to 1893, and that an assumption of $10,000,000,000 as the total value of U. S. manufactures in the year ending June 30, 1895, cannot be far from the truth.

Now comparing this vast sum with the value of our manufactured articles exported, we find that, in round numbers, for every dollar that the American manufacturer received from goods sold abroad, he received $75 for goods sold at home. It is evident from this that our export trade in manufactured articles is as yet a mere trifle compared with the volume of goods required to supply home consumption.

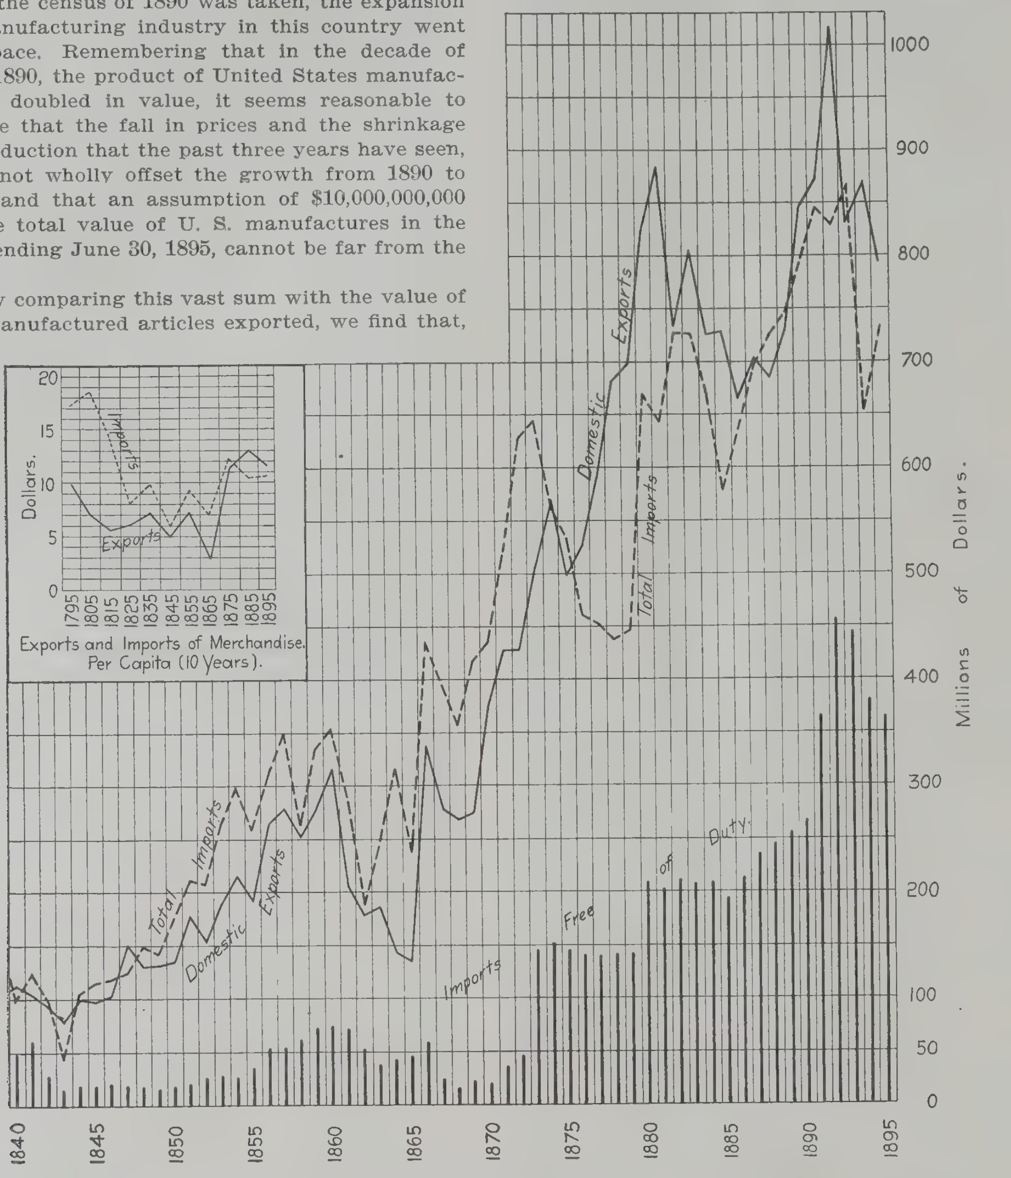

FIG. 1.—FOREIGN COMMERCE OF THE UNITED STATES, 1840 TO 1895.

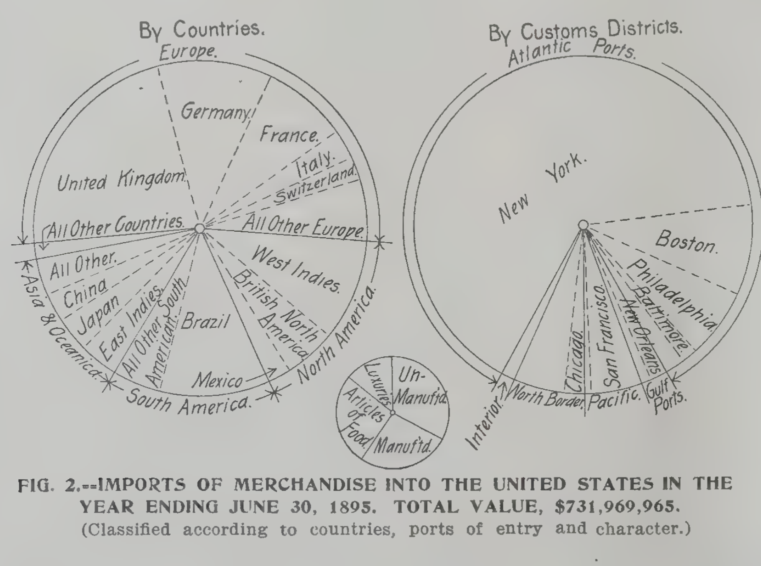

FIG. 2.--IMPORTS OF MERCHANDISE INTO THE UNITED STATES IN THE YEAR ENDING JUNE 30, 1895. TOTAL VALUE, $731,969,965.
(Classified according to countries, ports of entry and character.)

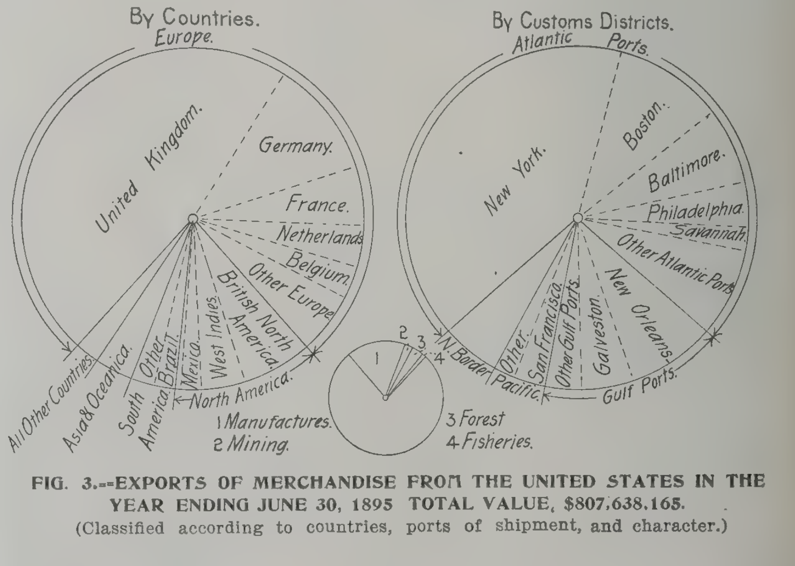

FIG. 3.--EXPORTS OF MERCHANDISE FROM THE UNITED STATES IN THE YEAR ENDING JUNE 30, 1895 TOTAL VALUE, $807,638,165.
(Classified according to countries, ports of shipment, and character.)

There is another profitable inquiry that we may make, and that is what proportion did the manufactured goods which we imported hold to those which were made and sold in this country. Turning again to the report of the Bureau of Statistics just issued, we find that the total value of manufactured goods imported into the United States, in the year ending June 30, 1895, was in round numbers $200,000,000. Thus if we accept the above estimate of the total value of U. S. manufactures ($10,000,000,000), and deduct from it the value of manufactures exported, we find that in round numbers there were $50 worth of American manufactured goods used in this country for every dollar's worth of manufactured goods which we imported.

And now let us see what volume of trade is being secured by the manufacturers of Europe outside of their own borders. Unfortunately, we have not at hand statistics showing the value of the exports of manufactured goods by the different countries of Europe. The total value of all exports by principal manufacturing nations is given as follows by Mulhall:

Nation.	Total value of exports in 1889.
Great Britain	£313,000,000
Germany	163,000,000
France	144,000,000
Holland	93,000,000
Russia	79,000,000
Belgium	50,000,000
Austria	44,000,000
Italy	38,000,000
Total	£924,000,000

We can only hazard a guess at what the increase or decrease has been during the past half dozen years and at what proportion of the above is manufactured articles. Suppose, however, that we assume 60% of the above to be manufactured goods and allow nothing for increase or decrease, we then obtain the present total annual value of European exports of manufactured goods (in U. S. money) at about $2,700,000,000. Certainly this is a huge enough total to offer an attraction to American manufacturers who find the home demand insufficient to absorb the entire capacity of their works. The United States exports of manufactures, as we showed above, now amount to about $135,000,000 per annum. Great Britain's exports of manufactured goods amounted in 1889 to, in round numbers, $900,000,000. Is it not reasonable to expect that the greatest manufacturing nation of the world may yet stand at the head in exports of manufactured goods?

There are some especial reasons which have been brought home to American manufacturers of late, why the cultivation of an export trade is especially desirable. We recall a notable case in the money panic of 1893, when one firm in this country which has a flourishing trade in many foreign lands, went quietly along in its business with no trouble for lack of money, while firms all about it, of equal or greater wealth, were at their wit's end to raise funds for current expenses. It needs no unusual gift of foresight to discern other reasons of financial trial in the future, and the manfacturer will be fortunate who in such periods can rely on foreign orders to keep his works running and on receipts from foreign sales to meet pressing liabilities.

Again, it is a fact which every intelligent student of commercial conditions recognizes, that a relatively small surplus of supply over demand has a marvellous effect in depressing prices. If American manufacturers can dispose abroad of their surplus products, constituting perhaps 1 per cent or 2 per cent or 5 per cent of their total product, it may serve to improve by even more than this percentage, the selling price of their entire output. This reason alone is sufficient to interest every manufacturer in the extension of American export trade. Even those who are not so situated as to be able to ship goods abroad may be benefited if some of their rivals turn their attention in this direction.

A question which will occur to almost everyone and which has already been debated more or less, is the effect which a change in our monetary standards may have upon export trade. If it is true, as has been generally claimed, that a change to a silver standard will lower rates of wages, measured on a gold standard, there appears to be good reason to believe that the American manufacturer would be in at least as good position to compete with his foreign rivals as he is at present. Further, in the general business depression which it is generally agreed must accompany a change in the monetary standard, manufacturers will have stronger incentives than ever to reach out for foreign customers while orders for the home trade are scarce.

Turning again to the figures of our foreign trade, we have deemed it worth while to reproduce herewith some very interesting diagrams just issued by the Bureau of Statistics of the Treasury Department. Fig. 1 shows graphically the total exports and imports for each year from 1840 to 1895. It will be seen that not till 1874 did our exports equal our imports; but that since that time they have been almost all the time materially in excess. The marvellous growth in the volume of our international exchanges which is shown by the figures, is not peculiar to the United States. Mulhall in 1889 declared that the volume of international commerce had increased forty-fold since the beginning of the century.

Fig. 2 shows graphically the total value of our imports and classifies them in three different ways: By the country from which they are brought; by the United States port at which they are entered; and by their character.

Fig. 3 shows similar information concerning our exports. The volume of trade of the different ports is a matter of especial interest. New York shows no signs of losing its supremacy as the great port of entry for imports, and it still controls nearly half the export trade. A most interesting feature is the growth of the export trade of the Gulf ports. It will be seen that New Orleans ships more than Baltimore, and Galveston more than Philadelphia. One more feature of the diagrams may be worthy of comment, and that is that Great Britain and Canada are our best customers, for they alone of all countries buy more of our goods than we buy of theirs.

Returning again in closing to the increase in the exports of our manufactured goods, it is interesting to find that the exports of the present year to Oriental ports show a gratifying increase over 1895. Since Jan. 1, of this year, 95,000 bales of American cotton goods have been shipped to China. This is a greater amount than we shipped in the whole of 1895 or 1894 or 1893. In 1892 we shipped 96,529 bales and in 1891, 142,668 bales. If the present rate is continued the shipments of the present year will eclipse our highest record. Nor is the proportion of the total trade in this quarter which America secures an insignificant one. Statistics of receipts at Shanghai show that from Jan. 1 to July 3, of the present year, there were received at that port 982,175 pieces of cotton drills and sheetings from American mills against only 613,500 pieces from all other countries. During the same period last year the figures were: American goods, 557,188 pieces; goods from all other countries, 338,471 pieces. It will be remembered that these goods are sold in direct competition with the products of the mills of Bombay, which not only have the advantage of surpassingly cheap labor and home-grown cotton, but are located within less than 5,000 miles of Shanghai by water, while the American goods must be carried by rail across the continent and then by steamer across the Pacific, making their total journey equal to half the circumference of the globe. If American manufacturers can successfully win trade under such adverse conditions, where shall limits be set to their achievements?

LETTERS TO THE EDITOR.

Relative Economy of Different Styles of Freehand Lettering.—Correction.

Sir: A typographical error appeared in your issue of July 30, in the article on "Relative Economy of Different Heights and Styles of Free-hand Letters," p. 79. In the latter part of the second paragraph the clause reading, "the height being increased 1-15 in. for each succeeding experiment," should read, "the height being increased 1-50 in. for each succeeding experiment." Yours respectfully, R. C. Vial.

Western Springs, Ill., Aug. 3, 1896.

The Relation Between Putrid Gases and Typhoid Fever.

Sir: In Engineering News of Aug. 6, a note appears regarding the relation between putrid gases and typhoid fever, referring to investigations by Dr. Giuseppe Alessi. This ground has been very well covered already by Sanarelli, and he is, I think, entitled to first honors in this line. His work at the Pasteur Institute, Paris, has been very fine. I referred to it in my "Water Supply," pp. 72 and 317. Very sincerely, Wm. P. Mason.

Hotel Kaaterskill, N. Y., Aug. 7, 1896.

Earthwork Slopes in the Tropics.

Sir: Reading the letter of Mr. Sylvanus Miller in Engineering News of June 25, and the editorial comment on same, these following suggestions occur to me:

From the language of the editor it is not clear that he intends to exclude the slope of embankment, when he speaks of earthwork slopes. It is possible that he refers to embankment slopes, as he mentions a slope of 1½ to 1, the usual slope of embankments. An earth embankment hardly becomes stable in the tropics, or anywhere else, except at a slope somewhat flatter than 1½ to 1. Mr. Miller plainly refers to the slope of excavations, and wherever the earth or other material is of such a nature that it will stand it is better to make the slope nearly vertical for excavations for railways, for the reasons given by Mr. Miller, less surface exposed to the rains, and the further reason of economical construction.

Specifications for the tropics appear to be written exactly as they are for the temperate zones. Slopes on railway excavations are made according to the nature of the material and the judgment of the engineer; but, in the end, more particularly according to the nature of the material. All of nature's laws are in full force in the tropics as elsewhere.

Mr. Miller in writing of canal construction, and that an earth slope for a canal will remain stable at any such slope as ½ to 1, will not be taken for granted by engineers. Has it been asserted by the builders of any canal that an earthwork slope of ½ to 1 was more stable than the usual slope (of 2 to 1) for canals?

One-half to 1 slopes of excavation for railways (in earth) are the rule throughout the greater part of Mexico, Arizona, New Mexico, Colorado, and I am told as far north as the Canadian Pacific Ry., but I think the slopes of ½ to 1 are hardly ever attempted in this same material for canals.

Probably the only material that would remain stable vertical would be solid rock, and we have an example of this in the Chicago Drainage Canal; vertical sides in solid rock excavation.

It is true that there is material here in Guatemala that in excavation will stand better at a slope of ¼ to 1 than flatter, because it is kept dry; but this same material if once subjected to the action of water is difficult to manage.

I have been in the tropics several years and have seen nothing to justify any hope of economy in attempting steep slopes for the Nicaragua Canal. No such hope is justified by the experience at Panama.

Charles Thornton.

Apartado 100, Guatemala, C. A., July 22, 1896.

Some Further Examples of Fictitious Accuracy.

Sir: I notice that in your editorial on "The Evils of Fictitious Accuracy," in your issue of July 30, you omitted from your summation one evil, which, although of not so much importance as those you mentioned, is still deserving of notice. I refer to the amount of time wasted by those engineers who are addicted to the habit of carrying out decimals to the bitter end when the data do not warrant it, or when such decimals have no real significance.

Take the case of railway earthwork. In spite of the fact that a difference in the cut of 1-10-ft. makes a difference of several cubic yards in the result, while a quite imperceptible bellying of the slope will make a like difference, perhaps in the same direction; some engineers will figure to the fraction of a yard, and use the approximate method of averaging end areas at that.

Some engineers seem to lose sight of the fact that the very object of their profession is to do well, safely, and for the least cost consistent therewith, what almost any fool could do very poorly and at a great expense. The real engineer will neither do careless and inaccurate work where fine work is needed, nor will he go to the other extreme of extravagant and useless refinement where only approximate results are required. Two illustrations of such "Ficticious Accuracy" have come to my notice, and they were such flagrant violations of engineering common sense that I deem them worthy of record.

Surveys and an estimate were made for a costly piece of work. A transit line was run and sufficient topography was taken to construct a tolerably accurate contoured plan, upon which a paper location was projected. Next came the profile plotted as accurately as could be done from such a paper location. The points thus determined were laboriously joined by means of a ruling pen and straight edge. After the grade line was established the center cuts were read from the profile and the quantities were computed by the average end area method, to fractions of a yard. The unit prices were, of course, mere estimates, and the amount of rock to be encountered unknown. No comment needed.

The other case was the gaging of a river some hundreds of feet in width. The engineer took fairly accurate observations by the method of rod floats. In computing the discharge (sometimes about 2,000 cu. ft. per sec.) he carried it out to the nearest hundredth of a cubic foot per day, and so reported it. It is doubtful if so eminent an engineer as the late Jas. B Francis, for example, would have felt justified in reporting the flow of a river to the nearest pint per diem, even had he been able to use a weir in the place of rod floats which reached anywhere from 1 in. to 2 ft. from the bottom of the stream. Yours truly, H. E. Abbott.

New York, Aug. 5, 1896.

An Exhibit of American Manufactures in China.

Sir: The Smithsonian Institution has received advice from the Department of State that it is the intention of the University of Peking to establish an exhibit of foreign machinery and mechanical appliances in connection with the Museum of the University. With a view to bringing this matter to the attention of the manufacturers and exporters of the United States a copy of this circular is sent to you, with the consent of the Department of State, with the request that, if you deem it proper to do so, you will publish it in the next issue of your journal.

Yours respectfully,
G. Brown Gour,
Acting Secretary.

Washington, D. C., August 10, 1896.

(The circular is as follows.—Ed.)

To the Honorable Richard Olney, Secretary of State,
Washington, D. C.

Sir: The Peking University, an important educational institution of this city, conducted under the auspices of the American Methodist Episcopal Mission, has recently opened in one of its buildings a museum which it is proposed to devote largely to the exhibition of foreign machinery and mechanical appliances. This museum is visited daily by increasing numbers of people of the better classes who are interested in acquiring some knowledge of foreign manufactures and inventions, and it is believed that it can be made an important means of advertising and introducing the products of American industry. The authorities of this museum would be glad to receive and exhibit working models, photographs or drawings of machinery and inventions or specimens thereof, such as plows, ships, firearms, cannon, electric machinery, cars, locomotives, wind-mills, looms, printing presses, wagons, engines, etc. Each exhibit which may be presented to them will be marked in Chinese with the name and address of the maker, together with the description and price if desired, and a capable translator will explain their use to inquirers.

This is an opportunity which manufacturers should be glad to avail of. Peking with a population of 600,000 is the literary and political center of the Empire. Advertising here should be more profitable than in any city in China. The Peking University is the center of a wide influence. It occupies commodious foreign buildings, lighted by electricity, and is attended by hundreds of young men in search of Western learning. The museum referred to is to be conducted solely for the purpose of increasing the usefulness of the University and attracting the attention of inquirers. Exhibits of the character above described will be gratefully received by it and will be advantageously employed for the benefit of exhibitors as circumstances will permit.

Correspondence on this subject and articles for exhibition may be sent to the Peking University, Peking, China, or to Mr. Charles H. Taft, Treasurer of the Peking University, No. 78 William St., New York City, and under an arrangement with the I. M. customs will be imported to China free of duty. The authorities of the University have applied to this legation for assistance in carrying out their plan, which with a view to such assistance I request that such publicity be given this despatch as the Department may deem fit.

Charles Denby, Jr.

Legation of the United States, Peking, June 5, 1896.

Why Does Wrought Iron Become Weaker and Cast Iron Stronger Under the Influence of Shocks?

Sir: Several inquiries of this nature have come to me during the past few months from people who have repeated successfully the tests recorded in the paper entitled "The Mobility of Molecules of Cast Iron," read at the Pittsburgh meeting of the American Institute of Mining Engineers, and first published in Engineering News of Feb. 27, 1896. The reply I have heretofore given—and now offer to others, through your columns—is this:

Assuming it to be a fact that wrought iron tends to become crystalline and brittle, when subjected to repeated shocks or prolonged stress, the tendency to such change may be due to the fact that the molecules of wrought iron are mechanically forced out of their natural order of arrangement by the hammering, forging or rolling of the metal. The "fiber" of rolled or forged iron is due to the mechanical "carding," as it were, of particles of iron and cinder, or scale, distributed throughout the mass; when examined under the microscope this is quite apparent.

When a shaft, axle, or other piece of forged or wrought iron is subjected, for a long period of time, to moderate stress or repeated vibrations, it is not inconceivable that the molecules—or particles of iron—thus mechanically disturbed and released from their enforced aggregations tend to rearrange themselves according to the laws of molecular attraction; such natural arrangement would be a crystalline one.

Molten cast iron, on the other hand, when poured into a mold and allowed to congeal, tends naturally to arrange the molecules according to this law, and, if a mass of fluid iron could be cooled with absolute uniformity thoughout the section, there would, I believe, be no difference in strength between a casting, whether annealed or not annealed; this result can be approximately accomplished by pouring a test bar in a mold so arranged that the bar in cooling is surrounded by a large mass of molten metal. Such a bar differs largely from a similar bar cast from the same metal and cooled in the ordinary way. Irregular cooling or rapid surface-cooling interferes with the natural crystallization of cast iron and so creates a condition of stress, which, in some cases, exceeds the elastic limit of the metal. A car wheel, for example, unless placed, while red hot, into an annealing pit, usually breaks in half, with a loud report, while cooling, but when properly annealed it is the strongest kind of casting.

A casting will gradually relieve itself of cooling strains if kept undisturbed for a sufficient length of time, and the "shocking system" simply shortens this time by enabling a quicker rearrangement of the molecules under the influence of taps, or vibrations.

The experiments recorded in my paper point clearly to this conclusion and the very large number of tests made afford a quantitative determination of the amount of strain existing in cast-iron test bars; this is found (as might be expected) to differ widely with different kinds of cast iron.

Discarding, for the moment, the wide difference in composition between nearly pure "wrought" iron and the complex alloy called cast iron, the difference in treatment of the two would seem to be quite sufficient to explain, in the manner herein given, why wrought iron tends to become brittle (if it does) under the influence of vibrations, while cast iron is actually strengthened, to a certain extent, by similar treatment.

A. E. Outerbridge.

16th and Hamilton Sts., Philadelphia, Pa., Aug. 4, 1896.

◆

How to Square a Circle and Rectify Its Circumference.

Sir: The following solution of the old problem of "squaring the circle," and rectifying the circumference gives remarkably accurate results and has suggested also a practical solution by a simple and handy instrument called the "Circle Rectograph."

The solution of the problem is based on the formula:

$$\left.\begin{array}{l}\text{Side of square with}\\ \text{same area as circle}\end{array}\right\} = R\sqrt{\pi} = \frac{2R^2}{\sqrt{R^2+\left[R-2\left(IV-V\right)\right]^2}}$$

in which R = radius of the circle, IV = the side of a square inscribed in it, and V = the side of a pentagon inscribed in it.

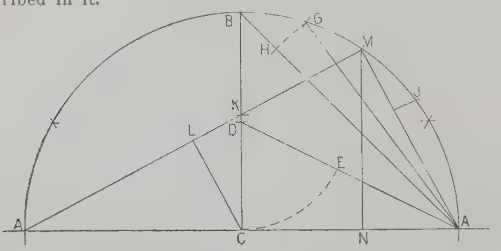

Fig. 1—Method of Constructing a Square Equal in Area to a Given Circle and Rectifying the Circumference.

In Fig. 1, let AA^1 be the diameter of the circle and C its center. Draw BC perpendicular to AA^1, lay off $CD = \frac{BC}{2}$; draw AD and lay off DE = CD; then AE will be equal to the side of regular decagon inscribed in the circle. With AE as a chord, lay off AJ and JG, then AG will be the side of a regular pentagon or = V in the formula. Draw AB and lay off AH = AG; BH will be IV − V in the formula. Lay off BK = 2BH = 2 (IV − V); CK = R − 2 (IV − V). Draw A^1M through K and CL perpendicular to A^1M;

$$A^1M = 2A^1L.$$

In the triangle CA^1K,

$$A^1L = \frac{(A^1C)^2}{A\,K},$$

$$A\,K = \sqrt{(A^1C)^2 + (C\,K)^2},$$

$$\text{Therefore } A^1L = \frac{R^2}{\sqrt{R^2+[R-2(IV-V)]^2}};$$

finally,

$$A^1M = 2\,A^1L = \frac{2R^2}{\sqrt{R^2+[R-2\,(IV-V)\,]^2}}$$

$= R\sqrt{\pi}$ = Side of square with same area as circle.

It remains to prove the exactness of the formula. Suppose R = 1. Then substituting the numerical values,

$$\sqrt{\pi} = \frac{2}{\sqrt{1+[1-2\ (1.41421-1.17557)\ ]^2}}$$

= 1.77245 which is the square root of π

To rectify the circumference: Draw MN perpendicular to AA^1 and draw AM; in the triangle AA^1M,

$$A^1N = \frac{(A^1M)^2}{A\,A^1} = \frac{R^2\pi}{2R} = \frac{R\pi}{2}$$

$= \frac{\text{Circumference}}{4}$; or Circumference $= 4A^1N$

Since the lines CL and AM are only explanatory, and lines BC, AD, AB, AG and MN need only be drawn so far as to mark the respective intersections, both constructions can be reduced as shown in Fig. 2, and in plain words we can say:

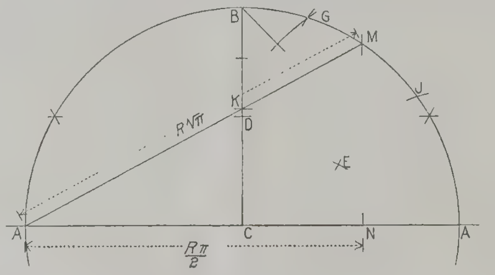

Fig. 2.—Abbreviated Construction.

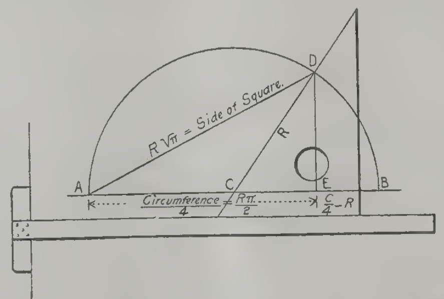
1. For squaring a given circle: On a line perpendicular to the diameter given lay off from the circumference toward the center twice the difference between the sides of the inscribed square and pentagon; the chord drawn from one end of the diameter and through the point found will be the side of a square having the same area as the circle.

2. To rectify the circumference: The line through the second intersection with the circumference of the chord drawn perpendicular to the diameter cuts off $\frac{\text{Circumference}}{4}$.

A glance at Figs. 1 and 2 shows that a plain triangle containing the angle AA^1M would give the point M at once, and this is indeed all that is required.



D
$R\sqrt{\pi}$ = Side of Square
R
A
C
E
B
$\frac{\text{Circumference}}{4}$
$\frac{R\pi}{2}$
$\frac{C}{4}-R$

Fig. 3.—Method of Application of the "Circle Rectograph."

But M can also be found by a triangle whose hypotenuse passes through the center of the circle. Since such a triangle need only be about half the size of the former, and for very exact constructions it is important to have the intersections at the best possible angles; that is, at right angles, I have preferred the latter triangle, and have named it the "Circle Rectograph." The "Circle Rectograph" and its application is shown in Fig. 3.

Directions for its use: Through the center of the circle lay the hypotenuse of the triangle by sliding the shorter edge along the T-square, parallel to the diameter given, mark the intersection D (formerly M) with the circumference and draw DE perpendicular to AB;

then will $AE = \frac{\text{Circumference}}{4}$;

AD = side of square with same area as circle.

The "Circle Rectograph" is made by Kolesch & Co., 155 Fulton St., New York city.

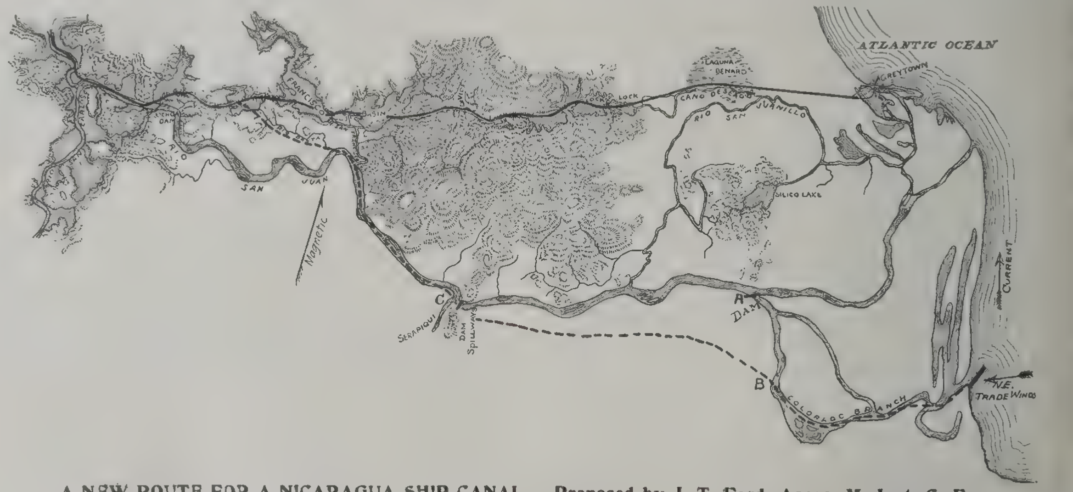
H. C. Fischer.

235 E. 19th St., New York, July 14, 1896.

◆

A Proposed New Location for a Nicaragua Ship Canal.

Sir: I hope you will forgive my troubling you again on the subject of the Nicaragua Canal, but it is my pet hobby to do my little best towards influencing some day, a real survey of the ground, and, if the Commissioners' able report is compared with my previous letters in your paper, of the following dates: July 6, 1893; June 20, Aug. 1 and 8, Oct. 10, 1895, as well as one in the "Railroad Gazette" of March 8, 1895, all antedating that report, it will be seen that nearly all my statements were justified. The Commissioners have, however, gone further than I had hoped, much to my regret, in giving the company such a fearful rating before the investing public and the U. S. Government, as to injure seriously, in my opinion, any chance for many years to come of regalvanizing the great project, either by private enterprise or government ownership; but it will be done some day, and Mr. Silvanus Miller's letter in your issue of June 25 has determined me to say another word in the hope that you will indulge me again and publish it. I am openly an enthusiast on the Nicaragua Canal, but an opponent of Mr. Menocal's route and of the methods of the old company; this attitude I have always held, as is shown by my letters above referred to. The skeleton sketch I send herewith is enough to convey my ideas on the Atlantic division without too much detail, I shall not touch on the Pacific terminus, as I think if Mr. Miller were familiar with the ground he would agree that we have but little choice there for a terminus within the limits of a reasonable expenditure. Salinas Bay is a very fair harbor, but so is the Harbor of San Francisco. As far as the Nicaragua Canal is concerned, it would cost too much to get there, and we must make the best we can of Brito.



A NEW ROUTE FOR A NICARAGUA SHIP CANAL. Proposed by J. T. Ford, Assoc. M. Inst. C. E.
(The proposed route is shown in dotted lines. The Menocal location is shown by a full line.)

Greytown, however, is quite a different problem, and there is ample room there for choice. I quite agree with Mr. Miller that the waters of the San Juan with their fearful freight of silt should be turned back to Greytown by cutting off the Colorado branch, say at or near point A; a simple pile and brush structure would do this easily, as it is practically at sea level and with little current for a great part of the year, and having the old channel to Greytown ready prepared, it would immediately scour out and again accommodate all the waters of the river as it used to do up to some 50 years ago. This feature has always formed part of my scheme, but now, when you have got the waters of the San Juan and their fearful sand drift at Greytown to leeward of us, for heaven's sake let them stay there and leave Greytown severely alone; we have then a channel with no CURRENT, and no DRIFT SAND, at sea level, practically all the way, already deep enough to float our dredges for 20 miles from the sea, and which we can deepen at small cost to any point which may be found convenient to use it. I select for argument sake point B as a likely point to leave the Colorado branch, and point C, the mouth of the Serapiqui River, as our first communication with the San Juan. Now, it will be said, we know nothing of the country between B and C. I only allow this, however, for argument sake, and if we do not know much, more shame is it, for the Canal Company. But I DO know that a favorable line can be got at SOME level between these points approximately, and proper surveys should have been made there. The mouth of the Colorado is certainly as good a place for a port as Greytown, though they are both pretty poor ones, but here at least we would be free of all drift, with marshy lagoons of great extent affording ample protection for shipping and capable of unlimited expansion for the sole cost of dredging under the most economical conditions. At point C it certainly will not be denied that a dam CAN be built at SOME elevation, say even with crest only 40 ft. above sea level, but I believe that 50 ft. above sea level could here be obtained. Whatever it may be, however, we obtain by this dam a certain amount of deeper slack water in the San Juan above, carving out ample spill-ways for discharging the river floods, in the hills on the north bank of the river at that point. Suppose now that we could not get up as high as Ochoa by using the present San Juan channel deepened and improved, because the crest of the Serapiqui dam be too low. We can, even then, leave the San Juan at any convenient point again, up the Rio Danta perhaps (I have been over this ground personally), and if we must have the fearfully dangerous high-level Ochoa dam (which I don't admit), and the San Francisco basin, with its appalling line of high mud embankments on soft mud bottoms, we can reach it conveniently in this way and adopt the Menocal route beyond, having gained the great advantages of avoiding the absurd Divide Cut, and the equally absurd proposition of making a practicable harbor of Greytown.

I write this all as a mere hypothesis, but I have a good deal of sound information to back it up nevertheless, and at least, is it sensible, on such a great work as this, to have left the south bank of the San Juan, from Ochoa to the sea, an absolute blank, as far as real surveys are concerned, or filled in with mere fancy work, as it has been on the company's plans, simply because of the petty squabbling and jealousy between Nicaragua and Costa Rica, about their boundaries and prospective rights of dominion over the canal, and the insistence on the part of Nicaragua, that the whole canal and its eastern terminus should be on her territory? But, of course, Mr. Menocal would never have got his concession at all if he had not made that promise.

My line for the proposed survey would certainly, if practicable, economize a great deal, and it is at all events worth the trouble of being proved to be wrong. The south bank of the San Juan should never have been ignored as it has been hitherto in such an important work, and by all means let us hope that the wise suggestions of the late able Commission will be adopted and the appropriation made by Congress for a proper survey. Yours truly,

J. T. Ford,
Asoc. M. Inst. C. E., Gen. Man. C. M. Ry. Co.
Cartagena, July 18, 1896.

◆

THE STRENGTH OF A CONCRETE SLAB was recently made the subject of an interesting test at the laboratory of the Massachusetts Institute of Technology, Boston, Mass. This slab was a section of flooring designed to be used in a courtyard for a dormitory building and which had to carry coal teams, etc. Brick arches had been specified for this floor, but on account of the lower bid for concrete flooring, the authorities decided to test it. In the test the slab was supported by four I-beams spaced 4 ft. 9 ins. c. to c. and was 5 × 14 ft. × 4 ins. with ¾-in. twisted steel bars spaced 6 ins. c. to c. and running lengthwise, and 3-16-in. bars running crosswise, 4 ft. 9 ins. apart, or directly over each I-beam. The composition of the concrete was 1 part Alsen's Portland cement, 1 part sand and 6 parts broken stone. The stone was crushed so that 2 parts passed a ½-in. ring and 4 parts a ¼-in. ring. Bricks were piled on in piers until a load of 16,770 lbs., or 724 lbs. per sq. ft. was obtained and a depression of 5-32-in. resulted. This load of course covered only the span between two I-beams. Next an impact test, consisting of dropping a timber weighing 164½ lbs. endwise onto the slab 20 ins. from the nearest I-beam and from a height of 7 ft. 10 ins. was made without causing any break or damage whatever. The third test was for shearing and consisted in thrusting with a screw jack against an I-beam laid transversly across the slab about midway between the I-beams, until a pressure of 20,700 lbs., with a deflection of 1 1-32 ins. was obtained before the concrete cracked. By means of the same screw jack a more local pressure covering an area of ½-in. × 9 ins. was tried. When placed so as to bring the pressure over two of the twisted iron bars the load borne was 6,200 lbs., and over one bar 7,700 lbs. were carried. It is stated that several faults of construction entered into this slab or else it would have shown still better results. Our authority for the above statements is the Ransome & Smith Co., of Chicago, Ill., which makes a specialty of this system of concrete and twisted iron construction.

THE DESIGN AND SPECIFICATIONS FOR THE FAIRMOUNT PARK BRIDGE.

In our issue of July 2 we published the accepted design made by the Phoenix Bridge Co., for the new bridge to be built by the Fairmount Park Transportation Co. in Fairmount Park, Philadelphia. After that date, as we briefly stated in our issue of July 16 (p. 48), a protest was presented to the Commissioners of Fairmount Park against the award of the contract, and the Commissioners referred the matter to Mr. Theodore Cooper, M. Am. Soc. C. E., for examination and report. As some of the questions at issue are of general interest to the profession, we print herewith several letters, from which our readers may gather the facts in the case and form their own conclusions.

For the easier understanding of the matter we may say that Gen. Russell Thayer, M. Am. Soc. C. E., is the Chief Engineer and Superintendent of Fairmount Park, Philadelphia, and is also Chief Engineer or Consulting Engineer (we are uncertain which), of the Fairmount Park Transportation Co., a private corporation which has obtained a franchise for the construction of an electric railway in Fairmount Park.

A little over a year ago General Thayer sent out invitations to bridge companies to submit proposals for this bridge, and several such proposals were received, but the final award was not made until June of the present year. We reprint the correspondence without further comment:

Philadelphia, Pa., May 31, 1895.

Pencoyd Iron Works, Pencoyd, Pa.:

Gentlemen: I should be pleased to receive from you on or before June 22 a proposal, accompanied by general plans and specifications for the construction of the superstructure of a steel bridge proposed to be constructed across the Schuylkill River, within the limits of Fairmount Park, by the Fairmount Park Transportation Co.

The enclosed blue print shows the general conditions existing and the general design of a structure that was prepared by me, but it is not intended to limit you to that particular design, except in so far as the length of spans, the elevation above water level, and the level and grade of the upper deck is concerned. It is quite probable that you may be able to submit a design much more attractive and more suitable.

The bridge will be a single deck structure, provided with a 10-ft. walk on north side of bridge, then a 40-ft. asphalt driveway for carriages, and next to the latter a double-track roadbed for extra heavy trolley cars. If considered desirable, the railroad portion of the structure may be separate and distinct from the driveway and footwalk, and the former may be from the latter by a space of 3 ft., but this is not required. Heavy ornamental iron railings will be required on each side of the roadway portion of the bridge, and on the outside of the railway portion.

In calculating the weight of highway portion of the structure in all its parts, the standard requirements heretofore adopted by the city of Philadelphia for such structures may be assumed, and in regard to the railway portion, the structure must be of amply sufficient strength to permit fast trains of heavily loaded cars to pass over same, with an ample factor of safety in all parts. These functions should be briefly stated in the general specifications.

Proposals will not include the masonry, and the company reserves the right to reject any or all bids. Any further information may be obtained by application to the Chief Engineer.

Yours respectfully,
Russell Thayer, Chief Engineer.

Address plans and proposals to Russell Thayer, C. E., Room 127, City Hall, Philadelphia.

◆

Philadelphia, Pa., June 10, 1895.

Poncoyd Iron Works, Philadelphia, Pa.:

Gentlemen: In order to give you ample time to properly complete specifications and proposals for the bridge proposed to be constructed across the Schuylkill River, for which you have some data, I have extended the time for receiving said proposals until 12 m., June 29, 1895. I enclose herewith additional data to be included in the requirements for the specifications for the structure.

Yours very truly,
Russell Thayer, Chief Engineer.

Memorandum of Specifications to be used in Designing the Superstructure of Bridge over Schuylkill River for Fairmount Transportation Company.

Lengths of Spans, Widths, Clearance, Etc.

The span lengths, elevation of grade line and clearance under the bridge to be as given on accompanying profile.

There is to be one sidewalk on north side of bridge 10 ft. wide, one roadway 40 ft. wide, both in the clear, and south of the roadway two tracks for electric cars, having a clearance of 12 ft. for each track.

General.

Cooper's Specifications for Highway Bridges, Edition 1890, to govern for unit stresses, quality of material, workmanship, etc., except as same may be modified below.

Structural Material.

All structural material to be soft steel except eye-bars, pins, I-beams and lateral rods, which are to be medium steel and except where it may be necessary to use rods requiring welding, in which case they are to be of wrought iron.

Roadway and Sidewalk Flooring.

The roadway and sidewalks are to be covered with asphalt pavement, carried on a solid steel floor, the asphalt wearing surface on the roadway to be 2 ins. thick and on sidewalk 1½ ins. thick, same being laid on bituminous concrete base or binder which shall be at least 3 ins. thick over highest point of the supporting steel work of the roadway, and 2 ins. thick over the highest point of the supporting steel work for the sidewalks, rivet heads not being considered in figuring the depth of concrete over the steel work.

Quality of asphalt wearing surface and bituminous binder to be as required by the specifications of the Dept. of Public Works for the City of Philadelphia.

Flooring for Railway Tracks.

Track rails to be laid on either white oak or long leaf southern yellow pine cross-ties, spaced with 6-in openings and secured to the steel work by ¾-in. bolts, through every third tie; the cross-ties being carried on longitudinal steel stringers.

Guard rails to be 6 × 8 in. yellow pine, dapped 1 in. over ties and bolted to every third tie with ¾-in. bolts, with additional bolts through splices.

Ties to be proportioned for an extreme fiber stress of 1,000 lbs. per sq. in., considering one axle load as being supported by three ties.

Hand Railing.

There are to be three lines of heavy ornamental iron railing, costing not less than $2 50 per lin. ft. of rail; one line on outer side of sidewalk, one line between roadway and electric car tracks, and one line on outer side of car tracks.

Loads to be Used in Calculations.

Dead Loads: The dead load is to include total weight of iron and steel in the structure, the weight of paving, wooden floor system, track rails, hand railing, etc. The weight of bituminus concrete to be taken at 140 lbs. per cu. ft., and the asphalt 95 lbs. per cu. ft., and all floor lumber at 4 lbs. per ft. B. M.

Live Load: In addition to the dead load, the structure is to be designed to carry 100 lbs. per sq. ft. on the roadway and sidewalks for the highway portion of the bridge, and 1,000 lbs. per lin. ft. on each electric car track distributed so as to produce maximum stresses.

In case two electric cars coupled on each track with loads of 20,000 lbs. on each axle distributed thus:

O—7 ft.—O——23 ft.—— O - 7 ft.- O.

or one wagon on the roadway with loads of 20,000 lbs. on each axle, wheels 5 ft. gage and 8 ft. wheelbase produce greater stresses in any of the members than loads specified above, then these members shall be proportioned for the concentrated loads as per diagram.

Unless the stresses in the trusses produced by live load when only partially covering the roadway and sidewalk transversely exceed by more than 10% the stresses produced by live load covering entire width of roadway and sidewalks, they need not be considered.

In case the partial loading produces stresses greater by 10% than the uniform loading covering the entire width of the roadway and sidewalks, then the truss members are to be proportioned so that the unit stresses under partial loading shall not exceed the specified unit stresses by more than 10% wind load.

The structure is to be designed to resist a wind pressure of 30 lbs. per sq. ft. on the vertical projections of each truss and railing, and the vertical projections of the floor system considered as a dead load and properly divided between the top and bottom lateral system, and in addition the top lateral system is to be figured for a moving load of 150 lbs. per lin. ft.

Limiting Thickness of Material.

No material less than ⅜ in. to be used except for fillers, and no rods having a smaller area than 1 sq. in. to be used.

◆

Commissioners of Fairmount Park, Philadelphia, Pa.:

Gentlemen: Under dates of May 31 and June 10, 1895, the A. & P. Roberts Co. received invitations to furnish a design and estimate for a bridge across the Schuylkill River in Fairmount Park. Said invitations were signed "Russell Thayer, Chief Engineer," and were accompanied by certain data and specifications for strength and loading to which the bridge should conform. In accordance therewith a design was prepared by the Pencoyd Iron Works, blue prints of which are herewith enclosed.

My attention was recently called by published articles in the daily papers, and also in the Engineering News of July 2 to the fact that the contract for this bridge had been let. I have no interest in the matter other than that of a citizen of Philadelphia, but deem it my duty to enter a protest against proceeding with the building of the structure, as shown in the articles above referred to:

I.—The bridge in question should contain three arches, not four.

II.—The masonry of the piers should be carried to the level of the roadway.

III.—The roadway, having considerable grade, will throw the arches out of a horizontal line, presenting an extremely bad effect in the adopted design.

IV.—The bridge as shown is much lighter and does not conform to the specifications issued by Chief Engineer Thayer in his invitation for proposals.

V.—At the time the present design was passed upon by your committee the plans were not in proper shape for a decision to be made, and General Thayer, as Chief Engineer, had in his possession information which it was his duty as General Thayer, Superintendent of Fairmount Park, to have furnished your committee. That the blue prints accompanying this communication were not shown the committee, and they had no knowledge of their existence.

I am credibly informed that no actual work has been done upon this bridge other than drawings, and I must respectfully urge upon you the reconsideration of the design for this structure, which can be made as the Washington Bridge in New York, an adornment to the Park, and not simply a means to carry a trolley line across a hole.

It is not a matter which can hereafter be remedied, and will stand an eye-sore, when there is no occasion for any such. Yours very respectfully,

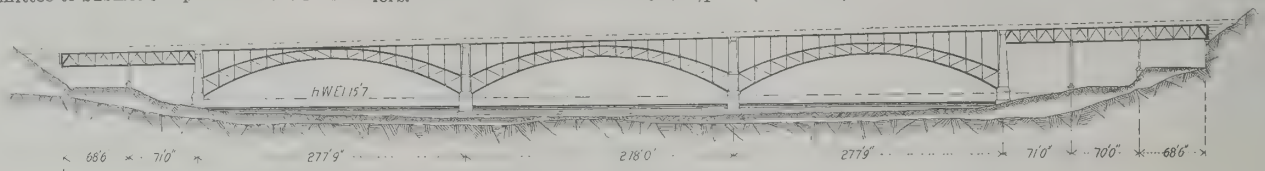
Percival Roberts, Jr.

261 South Fourth St., Philadelphia, July 9, 1896.

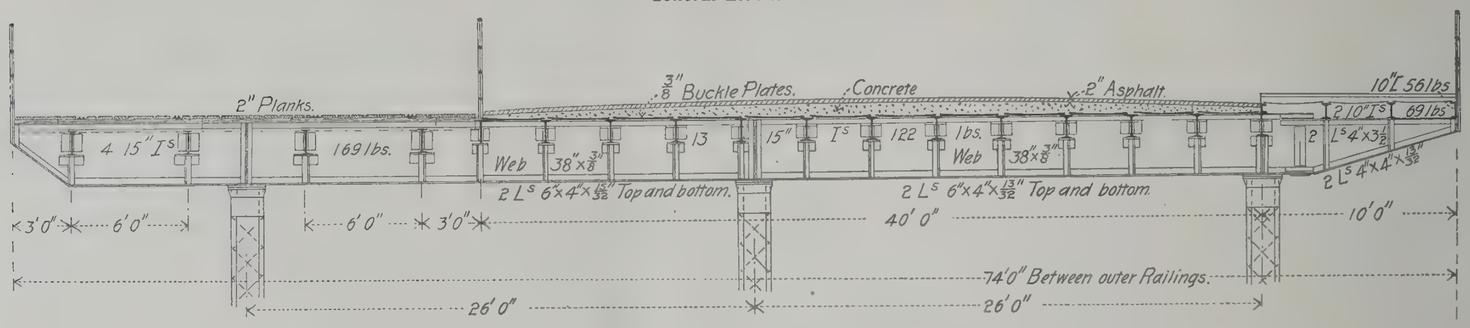
◆

Messrs. Geo. S. Webster and A. J. Cassatt, Committee of Fairmount Park Commissioners, Philadelphia, Pa.:

Gentlemen: Referring to the conversation had with Mr. Webster to-day, from which I understood that it is the purpose of your committee to submit the plans for the four-arch bridge now contracted for by the Fairmount Park Transportation Co. to an expert bridge engineer for examination and report, I beg to present for your consideration the following facts:



General Elevation.



Cross Section Showing Floor Construction.

DESIGN BY THE PENCOYD IRON WORKS FOR THE NEW BRIDGE OVER THE SCHUYLKILL RIVER IN FAIRMOUNT PARK, PHILADELPHIA, PA.

I still insist that a bridge containing three arches is the only proper bridge to be erected in the location in question. Your committee having decided not to open up this matter, I will not occupy your time with my reasons for the same, but only call your attention to the fact that the piers of the accepted bridge on the low water line occupy 62 ft. of the water way of the stream, and at the bottom 84 ft. So far as I know, at the time the plans were submitted to your committee for approval they were in very defective shape, as no strain sheet accompanied them, and very little data was shown.

It is, however, stated and made part of the contract that the standard specifications of the Phoenix Bridge Co. of 1895, for highway structures, shall govern the design of the bridge.

General Thayer stated on Tuesday last, at the meeting of the Committee on Plans and Improvements, that the accepted design of the four-arch bridge complied in all respects with the specifications issued by him under date of May 31 and June 10, 1895. I regret exceedingly to be compelled to say that this statement is entirely incorrect.

I have now to enclose you copies of the above-named invitations to tender for the bridge, and specifications to govern the design of the same. I now assert that the bridge as shown in the Engineering News of July 2, 1896, is a weaker and lighter structure than called for by General Thayer, and also that the specifications of the Phoenix Bridge Co. permit a structure which must, not only under General Thayer's specifications be condemned, but is also much lighter and weaker than would be permissible under the present practice and specifications of the City of Philadelphia.

I respectfully call your attention to the following points, upon which I base the above remarks:

Comparative Permissible unit strains in Highway Bridges, Dead and Live Loads Assumed Alike.

Specifications.	Cooper's 1890. Soft steel.	Cooper's 1890. Medium steel.	City of Phila.	Phoenix.
Plate and shapes in tension in trusses:				
Per sq. in.	12,330	14,800	13.500	15,940
In. % of Phoenix...	77.3%	92.8%	84.7%	100.0%
Plates and shapes in tension in floor:				
Per sq. in.	12,000	14,400	13.500	17,850
In. % of Phoenix...	67.2%	80.6%	75.6%	100.0%
Compressive unit stress not reduced for buckling:				
(A) Chords.				
Per sq. in.	13,300	16,000	12,000	15,940
In. % of Phoenix...	83.4%	100.3%	75.3%	100.0%
(B) Posts.				
Per sq. in.	11,660	13,330	12,000	15,940
In. % of Phoenix...	73.1%	83.6%	75.3%	100.0%
Compressive unit stress reduced for buckling for l ÷ r = 50.				
(A) Chords for Cooper's, fixed ends for Phoenix:				
Per sq. in.	10,670	12,800	......	14,900
In. % of Phoenix...	71.6%	85.9%	....	100.0%
(B) Posts for Cooper, hinged ends for Phoenix:				
Per sq. in.	8,330	8,670	......	13,990
In. % of Phoenix...	59.5%	62.0%	....	100.0%
Lateral Bracing:				
Per sq. in.	15,000	18,000	......	25,000
In. % of Phoenix...	60.0%	72.0%	....	100.0%

Thayer's, Cooper's 1890 Modified.	Phoenix.
Quality of material: Soft steel, 54,000 to 62,000 (Clause 131). If medium steel used (see Clause 109). All holes reamed; all edges planed. Thayer distinctly specifies soft steel.	Quality of material: Medium steel reamed and planed, over ⅝-in. thick, 60,000 to 68,000 lbs. (Clause 66 and 67-92).
Live Load: 100 lbs. per sq. ft. No material less than ⅜-in. to be used except fillers.	Live Load: 100 lbs per sq. ft. floor, 80 lbs. per sq. ft. trusses. No material less than ¼-in. (Clause 31).

From the above data it will be seen that the proposed bridge is too high in its unit strains. The quality of the material does not conform to the specifications of General Thayer, nor to Cooper's, for the same quality of material. The workmanship does not conform to the specifications of Cooper. The trusses are designed for a live load 20% lighter than called for by Thayer. The thickness of material is less than permissible by Thayer.

If, therefore, the Phoenix Bridge Co.'s specifications are correct for the designing of this bridge, the specifications of Mr. Cooper, of Mr. Cooper modified by General Thayer, and the practice of the city of Philadelphia, and other first-class cities for municipal work of this character are incorrect, and should be modified in the interests of taxpayers.

I contend that the proposed bridge due to its position and liability to full loading should be designed with the same factors of safety as would be used in any other first-class municipal work, and respectfully claim that the above-given data conclusively proves that such is not the case.

If the four-arch bridge must be used, then let it be proportioned either under General Thayer's specifications as issued, or in conformity with the practice of the Engineering Department of the city of Philadelphia.

Yours truly, Percival Roberts, Jr.

Philadelphia, Pa., July 16, 1896.

◆

Commissioners of Fairmount Park, Philadelphia, Pa.

Gentlemen: In compliance with the request of your Sub-Committee on Plans and Improvements, I have made an examination of the general plans for the Fairmount Park bridge proposed to be built by the Fairmount Park Transportation Co.

Your sub-committee has furnished me with copies of the communications from Mr. Percival Roberts, Jr., and other papers relating to this work. The Phoenix Bridge Co. has sent me copies of the general plans of their proposed bridge and their specifications under which they propose to construct it. The general plans consist of three sheets of drawings, as follows, viz.:

1. A general elevation and cross-section at the centre of one arch.
2. Elevation of one arch, its strain sheet and plan of the metal floor.
3. Plan of cross floor beam and stringers.

As shown by these plans the structure consists of a metal approach on the west bank 180 ft. long, four main river spans each 208 ft. long between centers of piers, and a metal approach on the east bank 210 ft. long, making a total length of steel structure 1,222 ft. The carrying trusses of the approaches are lattice girders resting on vertical points. The main river spans are steel arches springing from masonry piers a few feet above high water line, and having a rise at the center of about 40 ft.

The total width of the structure is 79 ft. 3 ins., consisting of a sidewalk on the north side 12 ft. in width, a driveway 40 ft. wide, and a separate division 27 ft. 3 ins. wide reserved for a double-track electric railroad. The sidewalk and driveway are to be paved with asphalt. The approaches are to have a grade of 2.56%, and the main spans 1.202%, all rising towards the eastern bank.

The license under which this bridge is to be constructed says:

> The said bridge over the River Schuylkill shall be a substantial and ornamental structure of steel or iron, with stone piers and abutments, and the plans, materials and construction thereof shall be subject to the approval of the Committee of the Commissioners of Fairmount Park on Plans and Improvements. Proper provision shall be made on the said bridge for passages of carriages and foot passengers, and no charge shall be made for their passage over the said bridge.

The only question that has been raised in reference to this requirement is whether the proposed bridge is a "suitable and ornamental structure," not whether it is the most substantial and ornamental, nor whether a more substantial and ornamental structure could not have been made. Under a general requirement like the above, a reasonable interpretation must be taken.

Capacity and Strength of the Structure.

This bridge has been proportioned for the following requirements:

1. The floor beams and stringers are to carry a load of 100 lbs. per sq. ft. over all parts of the sidewalk and driveway, or a 20-ton load on a wheel-base of 9 ft. on any part of the driveway; and for 1,000 lbs. per lin. ft. of the railroad tracks or an electric car weighing 25 tons loaded, followed by another car weighing 20 tons loaded, on a total wheel-base of 78 ft.
2. The trusses are to carry the full area of the sidewalk and driveway over the whole span loaded with 80 lbs. per sq. ft., and 1,000 lbs. per lin. ft. over each railroad track.

I consider the above requirements for the loading satisfactory and sufficient. In addition it is required that all parts of the structure shall be proportioned under these loadings so that the maximum strain shall not exceed those allowed by the Phoenix Bridge Co.'s specifications. As far as is shown upon the general plans submitted, these allowed strains have not been exceeded.

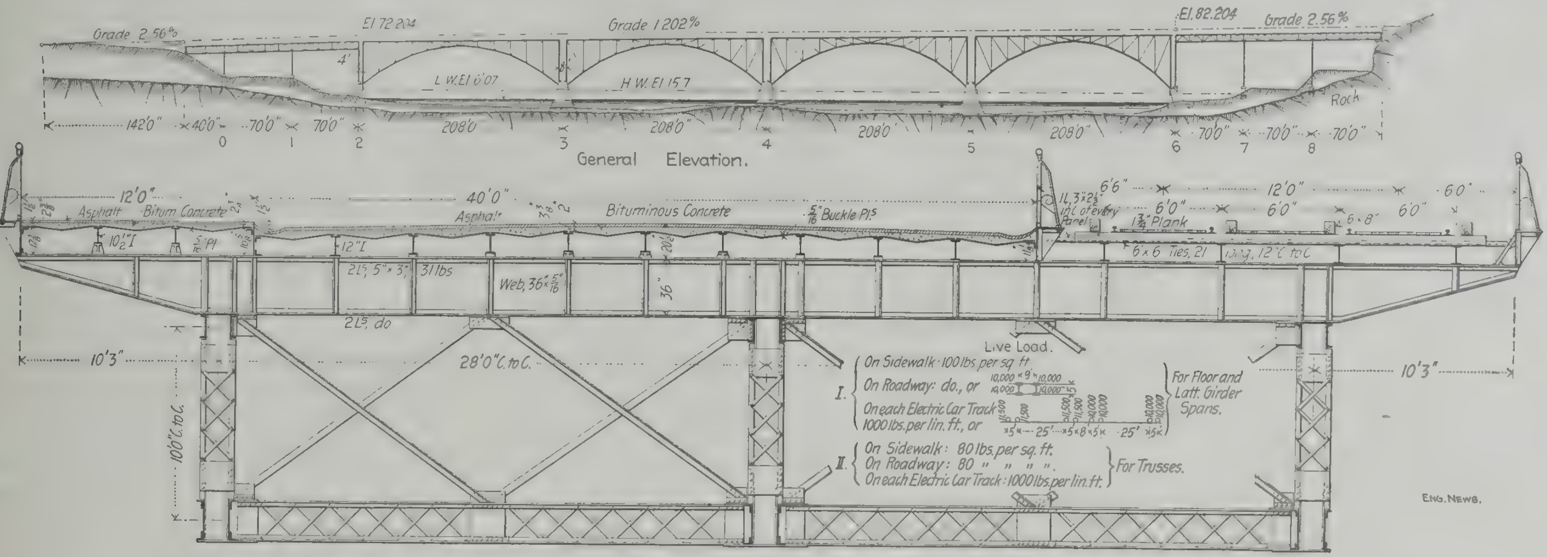
From the point of view of capacity and strength, the proposed bridge can be considered a substantial structure. There are, however, certain features of the structural parts of the work which I would recommend changed or modified:

1. The buckle plates of the driveway should be crowned upwards instead of downwards, as they can then be better drained and will be less subject to deterioration. They should also be riveted to the beams instead of bolted.
2. There should be at each side of the driveway a metal curb of an approved form.
3. The gutters should be shaped as is customary and not of the depressed form as shown. They should be drained into a pipe system leading to and down along the piers into the river. They should not drain directly into the river to the annoyance of persons using the river, or so as to permit the wind to blow it upon the structural work.
4. At the junction of spans, where expansion spaces are needed, an approved form of expansion joint should be placed in the paving that will be smooth and noiseless under the passage of vehicles.
5. There should be provisions made for putting now or at some future time hydrants at suitable distances, for washing the pavements.
6. The handrailing is not satisfactory from either the point of strength or appearance. This bridge will be liable

to have crowds upon special occasions, like boat races. which would tax severely the strength of the handrailing. It should therefore be about 4 ft. 6 ins. high above the sidewalk and of unquestioned strength. It is due to the structure that it should be an ornamental one, both from its effect upon the general external appearance of the whole structure, but also as seen from the roadways.

General Appearance of the Structure.

Where all conditions are equal, a three-spanned arch bridge is generally considered a more pleasing structure than one of an even number of spans. I estimate that under the same requirements, allowing for the saving of the cost of one pier, three spans at this point would have cost about $20,000 more. The location of the present piers was determined by conditions of the channel. The west abutment and the west river pier are now under way.



General Elevation.

Cross Section at Center of Span.

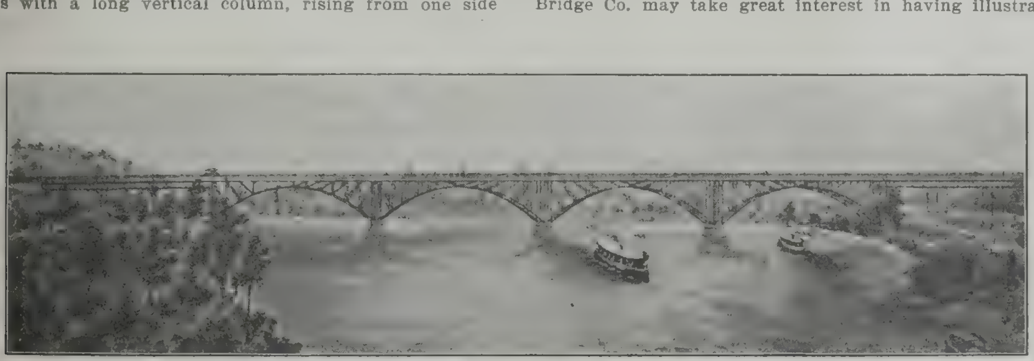
DESIGN BY THE PHŒNIX BRIDGE CO. FOR THE NEW BRIDGE OVER THE SCHUYLKILL RIVER IN FAIRMOUNT PARK, PHILADELPHIA, PA.

I do not consider the selection of three spans instead of four as of sufficient importance, under the circumstances, to recommend any change. I think, however, that certain changes are necessary in the proposed plan to give the structure that satisfactory and pleasing appearance that its location demands.

1. The general outline of the main spans at the top is a straight line. It will appear from a distance as curved downwards and would be very unsatisfactory in looks. This line should be cambered downwards about 2 ft. at the middle of its length, giving the skyline an actual curve of 2 ft. in 800. This curve on the roadway should be gradual, merging into the grades of the approaches. The effect of the two approaches, both inclined upwards and east, can be modified by the trees on the bank.

2. The fascia shown on the plans is too small and meagre in its treatment. The fascia, cornice and handrailing should be treated as a whole both for strength and architectural effect. Plates LVII. and LVIII. of the "History of Washington bridge over the Harlem River, New York," shows the fascia, cornice and handrail of the bridge. While this is of greater magnitude than required for the bridge under consideration, it shows the desirable method of treatment.

3. Weakness of look at the ends of spans. Each span ends with a long vertical column, rising from one side of the piers, so that at the point where the eye expects massiveness, there are only two long slim posts. Slender masonry piers extending above the footings of the arches would have relieved this effect on the river piers, but at the abutments a more massive work would have been required.



PERSPECTIVE VIEW OF DESIGN FOR FAIRMOUNT PARK BRIDGE.
By the Phœnix Bridge Co.

I think this can be largely remedied by making the metal work over the piers of a more massive looking character, without the use of false ornamentation. In like manner at the ends of the bridge the single light post and the sudden break at the lattice girder approaches detracts very much from the dignity of the structure. This can be remedied by making the approach spans next the arch spans, half arch spans corresponding in form to the main spans.

If the suggestions above indicated are carried out properly, I think you will have obtained for the City of Philadelphia a substantial and ornamental structure, and a suitable Park bridge. Yours respectfully,

Theodore Cooper, Consulting Engineer.

New York, July 30, 1896.

We reprint herewith from our issue of July 2, the design for this bridge presented by the Phoenix Bridge Co., and also show on the same scale and in the same style the design which was submitted by the Pencoyd Co. with its bid, in order that our readers may more readily compare the two. In accordance with our usual custom we have submitted proofs of the above matter to the parties interested, with an invitation to present replies or comments, for publication in connection with the above; and we have received the following letter from the Phoenix Bridge Co.:

◆

Sir: I am quite familiar with the correspondence of Mr. Percival Roberts, Jr., Vice-President Pencoyd Iron Works, in connection with the bridge now being constructed over the Schuylkill River in Fairmount Park, Philadelphia, which correspondence you kindly forwarded to me; I have also seen considerable additional correspondence that Mr. Roberts has seen fit to address to a number of Philadelphia city officials and copies of which were given to reporters of Philadelphia daily papers. The Phoenix Bridge Co., having been engaged to build a combined highway and trolley bridge of stated dimensions and under given specifications I have not felt at liberty to discuss these requirements either privately or publicly. After a careful examination of Mr. Roberts' letters I fail to find any scientific matter of public interest. The Pencoyd Bridge Co. may take great interest in having illustrated in your journal alongside of the Phoenix Bridge Co.'s plan their ideas of proper plan and length of spans, which might be adaptable to another location, but in the present case it is ruled out absolutely as unsuitable and not acceptable to the Park commissioners (see Russell Thayer's letter of invitation of May 31, 1895, above). The local conditions are such that the four-span crossing is necessary and was so fixed upon as long ago as 1894.

There are many specifications to choose from in undertaking to design a bridge, and their differences in some particulars can readily be expressed by percentages, without, however, enlarging our knowledge of their respective merits. This is all Mr. Roberts seems to have shown and in a manner that is manifestly misleading. Moreover, in comparing specifications, Mr. Roberts is also misleading and unreasonable. He compares the Phoenix Bridge Co.'s specifications, prepared in 1895, after several years of experience in the manufacture and use of steel construction, with the specifications of Theodore Cooper and of the City of Philadelphia prepared as early as 1890, when steel was first being used and its behavior during manufacture and in service somewhat uncertain. Mr. Theodore Cooper has a new highway bridge specification in press and the City of Philadelphia is changing their specification to agree with experience. Mr. Roberts, in making his comparisons, also used the limiting unit stresses, without bearing in mind that well known clause, which Mr. Theodore Cooper, from his wide experience has thought necessary to print on the outside cover of each copy of his specifications: "The most perfect system of rules to insure success must be interpreted upon the broad grounds of professional intelligence and common sense."

The Phoenix Bridge Co. try to interpret their own specifications on these lines and also any other specification which they are called upon to use from time to time. If Mr. Roberts had so desired he could have convinced himself by an examination of our detail stress sheet, giving sizes, etc., prepared several weeks before he saw fit to criticise the plan, that in no case have we used the limiting strains he finds, but have used our "common sense and professional intelligence" in designing and detailing the particular bridge under consideration, bearing in mind the duties it must perform. That we have not erred in our conclusions and judgment is borne out by the report just made to the sub-committee of Fairmount Park commissioners by their consulting engineer, Theodore Cooper, which you have reprinted.

Mr. Roberts' criticisms are answered in the following portion of Mr. Cooper's report:

> Capacity and Strength of the Structure.—This bridge has been proportioned for the following requirements: 1. The floor beams and stringers are to carry a loading of 100 lbs. per sq. ft. over all parts of the sidewalk and driveway or a 20-ton load on a wheel-base of 9 ft. on any part of the driveway; and for 1,000 lbs. per lin. ft. of the railroad tracks or an electric car weighing 25 tons loaded followed by another car weighing 20 tons loaded, on a total wheel-base of 78 ft.
>
> 2. The trusses are to carry the full area of the sidewalk and driveway over the whole span loaded with 80 lbs. per sq. ft., and 1,000 lbs. per lin. ft. over each railroad track.
>
> I consider the above requirements for the loading satisfactory and sufficient. In addition it is required that all parts of the structure shall be proportioned under these loadings so that the maximum strains shall not exceed those allowed by the Phoenix Bridge Co.'s specifications. As far as is shown on the general plans submitted, these allowed strains have not been exceeded. From the point of view of capacity and strength the proposed bridge can be considered a substantial structure.

Mr. Cooper's suggestions regarding number of spans, grade, pavement, cast curbs, gutters, hydrants, drainage, hand railing, auxiliary masonry piers, etc., are all matters in which the Phoenix Bridge Co. have no voice or interest, these points being determined by the committee of Fairmount Park or their representatives.

As I have intimated before, I find nothing to discuss in Mr. Roberts' letters that would be of great interest to your readers, and I can find no excuse or reason for their publication.

In June, 1895, we submitted tenders for the construction of the bridge in exact accordance with the letter and specifications received by Mr. Roberts (see copies above). In this competition with three other companies we were the lowest bidder and were so advised, and Mr. Roberts' interest as a bidder ceased. About a year later we were asked to enter into a contract for the construction of the bridge, various modifications having been made in loading, width of sidewalk, width of trolley portion, total length of structure, wooden floor, etc. After considerable discussion we finally entered into an agreement to furnish the metal work in place. After we were well under way Mr. Roberts took up the matter as "a disinterested taxpayer of the city of Philadelphia," intimating that the loading was light, the Phoenix Bridge Co.'s specification not good practice, there should be only three spans, etc., etc.

In view of Mr. Cooper's report, his rights as a taxpayer do not appear to have been trampled upon to any serious extent.

I am able to say without qualification that the bridge as designed, in my judgment, will conform to best modern practice, and when completed will be one of the most substantial and ornamental highway bridges in the country. The photograph which I send you herewith shows the bridge as it will appear when completed. I shall be pleased to have an opportunity to make to the Engineering News, at a later date a full representation of the special features and details of this bridge, which I believe will be of general interest.

Respectfully yours,
John Sterling Deans,
Chief Engineer, Phoenix Bridge Co.
Phoenixville, Pa., Aug. 8, 1896.

◆

TESTS OF NON-CONDUCTING COVERINGS FOR BOILERS AND STEAM PIPES.

The Boston Manufacturers' Mutual Fire Insurance Co. has issued a report by Prof. Chas. L. Norton, of the Massachusetts Institute of Technology, on the relative efficiency of different commercial coverings for steam pipes. His tests were made by a new method which consists in filling the pipe under trial with oil and heating the oil by a wire immersed in it which carries an electric current. The amount of heat radiated from the pipe is equal to the heat furnished by the current, which may be computed from the readings of a voltmeter and an ammeter. The accompanying tables give the results obtained:

Results of tests of Non-Conducting Steam-Pipe Coverings

Table I.—Test.—Temperature in the Pipe, 381.7° F., Corresponding to Steam of 200 lbs. Absolute Pressure; Temperatude of the Room, 72° F.

No.	Name.	Thickness, ins.	British thermal units per sq. ft. pipe per minute.	Ratio of heat loss to loss from bare pipe.	Weight, ounces per ft. of length.
1.	Nonpareil cork	0.90	3.04	0.254	21
2.	Magnesia	1.12	3.40	0.284	24
3.	Air cell No. 1	1.12	3.58	0.300	23
4.	Air cell No. 2	1.25	3.40	0.284	50
5.	Magnabestos	1.12	3.84	0.321	48
6.	Fire felt	1.00	3.99	0.333	46
7.	Calcite	1.25	5.02	0.423	29
8.	Bare pipe	....	11.96	1.000	..

Table II.—Temperature in the Pipe, 239.4°, Corresponding to Steam 10 lbs. above Atmospheric Pressure; Temperature of the Room, 72°.

No.	Name.	Thickness in ins.	British thermal units per sq.ft. pipe per min.	Ratio of h't loss to loss from bare pipe.
1.	Nonpareil cork	0.90	1.44	0.232
2.	Magnesia	1.12	1.59	0.262
4.	Air cell No. 2	1.25	1.58	0.261
5.	Magnabestos	1.12	2.32	0.383
6.	Fire felt	1.00	2.40	0.395
8.	Bare pipe	..	6.06	1.000

No. 1 was furnished by Stone & Duryee, Nos. 2 and 5 by Keasbey & Matthison, Nos. 3 and 4 by Asbestos Paper Co., No. 6 by H. W. Johns Co., and No. 7 by Phillip Carey Co.

Full details of the method of conducting the tests are given in Prof. Norton's report. The results given above are averages obtained from 5 to 15 tests of each specimen, and the variations in individual tests were so small that the values of the ratios of efficiency can be depended on as correct within ½ %.

The circular contains also some important information concerning the liability of wooden laggings of cylinders and boxing of steam pipe to char and take fire. Wooden coverings of cylinders and steam pipes are apt to become completely converted into charcoal, and this may take fire immediately upon the entrance of air through the outer coving.

A caution is given concerning the use of mineral wool as a steam-pipe covering, as follows:

> It serves only as a non-heat-conductor when in a very light and fluffy condition holding entrapped air. It is liable to be consolidaed by the vibration of the factory, leaving the upper part of pipes exposed, while the lower side is only guarded against radiation by this material becoming more and more solid and therefore less fit for its purpose. But this is not the worst. It is very dangerous stuff to handle. The fine needles getting under the nails will produce very injurious effects, and it is not safe to handle this material even in a laboratory without carefully protecting mouth and nose from the dust, which when breathed has produced hemorrhage. Much of this slag also contains sulphur or other elements which when wet or even dampened by escaping steam become very corrosive. Another type of a similar kind is known as Rock Wool. This appears to be made from glass and is therefore without corrosive effect, but is even more dangerous to handle than the mineral type. We therefore give this warning against the use of mineral and rock wool whenever offered to any of our members for covering pipes, and when used for any other purpose it should be handled with the greatest caution.

An addendum to the circular states that the caution regarding rock wool applies only to the use of the substance in its loose condition. A covering is made in which the material is so held in containing covers as to make it probably quite safe to handle and free from liabilty to injury by vibration.

Concerning asbestos and other materials used for coverings, the circular says:

> Asbestos is one of the most valuable substances ever discovered for use in making pipe coverings and boiler laggings, but it is not because the asbestos itself is a non-conductor of heat; on the contrary, in a solid or compact condition, it is rather a quick conductor of heat, and must therefore be used merely as a bond for other substances or medium for holding entrapped air. Asbestos being an incombustible and fibrous substance may be and is used as a bond for holding magnesia, and other non-heat-conducting substances in position. It is also used in the manufacture of the Air Cell Covering for the purpose of holding a very large amount of entrapped air. In this way it serves a purpose for which it would be wholly unsuitable by itself, as it is liable to become more and more solid under vibration, even if first used in a porous or fluffy condition without combination with other substances.
>
> The properties of magnesia in a loose condition holding entrapped air, the properties of what is known as fossil meal which is the diatomaceous earth, found under peat bogs, and the properties of cork in retarding the radiation of heat were well established by our previous investigation. The properties of air entrapped in a finely divided form, that is to say, entrapped in a material in which there can be little or no circulation of the air, have long been known. Hence success in making a pipe covering or boiler lagging has consisted in the combination of a bonding material of an incombustible kind, notably asbestos fiber, so as to hold the maximum amount of loose magnesia, loose fossil meal or entrapped air in the encasement which can be put on the outside of the pipe, and maintained without being impaired by vibration, or from other causes.

THE DETAILED COST OF 8-IN. PIPE SEWERS AT ITHACA, N. Y.

We have received from Mr. H. N. Ogden, Jun. Am. Soc. C. E., Chief Engineer of the Sewer Commission of Ithaca, N. Y., some figures relating to the detailed cost of 8-in. pipe sewers on 13 streets in that city, comprising a total length of 17,163 ft. The figures are given in the accompanying table and are supplemented by the following explanatory notes:

> The column of cost of labor is based on observed number of laborers at the following assumed prices, which may vary a little from those actually paid: Foreman, $2; laborers, $1.35; masons, $3.50; tenders, $1.50; pipe layers, $1.50; teams, $3.50. Pipe, 12½ cts. per ft., with Ys 25 cts. each additional. Brick, $8. No amount for superintendence or profit is included. Teams were used for hauling pipe and cement from cars, and for cleaning up the streets. Amount not very regular, and probably partly inaccurate. The cost of manholes was made up sometimes by adding cost of brick and cement to labor, and sometimes by multiplying the depth by a determined amount per foot of depth. The manhole covers were bought separately, and are here estimated at 1½ cts. per lb. Cement was furnished by the city and delivered to contractor on the car. The cost to city was 95 cts. per bbl. The amount of cement used ranged from 120 to 243 ft. of laid pipe per bbl. Pipe was deep-socket pipe, and is estimated at 12½ cts. per ft. on cars here; all 8-in. The average cut given is found from the average of the different cuts for different distances along the trench, or is the true mean cut. Underdrains, where used, were furnished by the city; cost of labor only is included on Green St. Cost per foot per foot deep is found by dividing cost per foot by average cut. It eliminates the difference in the depth of trenches, and gives a fair comparison between the cost of pipe laying in the different streets, and between the different foremen. Cayuga St. only is paved (brick on 6 ins. of concrete) and the cost of repaving is not included. The other streets have a gravel surface. There were three gangs all and four gangs half of the month during which time the above work was done.

Detailed Cost of 8-in. Pipe Sewers in Sec. 7 of the Sewerage System of Ithaca, N. Y.

Street.	No. of day's work.	Cost of labor.	Cost of teams.	No. manholes.	Cost manholes.	Cost of manhole covers.	Cost of cement.	Cost of pipe.	Total cost.	Length laid, ft.	Cut, ft. Max.	Cut, ft. Min.	Cut, ft. Ave.	Cost per ft.	Cost per ft. per ft. deep.	Remarks.

◆

RULES FOR THE SANITARY PROTECTION of the water supplies of eight cities and nine villages have been established by the State Board of Health of New York in the past few years. The original authority for making such rules was given by Chap. 543 of the Laws of 1885, which required the approval of the County Judge of the county in which the waters are located. By Chap. 661 of the Laws of 1893, and amendments thereto, the rules established by the board take effect without the approval of local Judges. The cities for which rules have already been established are New York, Brooklyn, Rochester, Watertown, Syracuse, Elmira, Mount Vernon and Newburgh; the villages are Norwich, Cobleskill, Ilion, Fort Edward, Sing Sing, New Rochelle, Coxsackie and Skaneateles.

◆

THE RELATIVE EFFICIENCY and cost of plumber's work has been investigated in detail by the London "Lancet" through a special commission appointed for that purpose. The commission gives three reasons for the large number of unsanitary houses: (1) The "prevailing indifference and consequent ignorance of all classes" regarding sanitary appliances; (2) bad work and cheap material as a result "of putting such work up to the distorted competition of all who may choose to tender for it;" (3) "the cost of rectifying sanitary work." After discussing these three reasons the report is chiefly taken up with a description of the plumbing in three imaginary buildings, with detailed estimates of the cost of making it good. Floor plans of the buildings are presented and many sketches of plumbing details showing how not to and how to do it. The report is published as a supplement to the "Lancet" for July 4, 1896.

THE AMERICAN LINE STEAMSHIP "ST. PAUL," on Aug. 14, arrived at Sandy Hook in 6 days and 31 minutes from Southampton. The course covered was 3,046.1 knots and the average speed was 21.08 knots per hour. On Aug. 13 she made a record of 530.8 knots. The highest horsepower developed was 20,800, with a highest steam pressure of 198 lbs. per sq. in.; the average revolutions of the screws were 90½ per minute, with a maximum of 93 revolutions. The sea was generally smooth and weather favorable, with some fog, which caused a slight delay. The "St. Paul" thus lowers by one hour and 53 minutes the record made last week by her sister ship, the "St. Louis," and lowers her own previous fastest trip by one minute less than five hours. The average coal consumption on the "St. Paul" was 315 tons per day.

◆

THE HAMBURG-AMERICAN STEAMSHIP "Fuerst Bismarck" has made a new record of six days, 9 hours and 43 minutes, from Southampton to Sandy Hook. The average speed was 19.85 knots per hour. Her best previous record was 6 days, 10 hours and 32 minutes. The White Star steamship "Britannic" also lowered her former best record, of 19 years ago, by reaching Sandy Hook from Queenstown in 7 days, 7 hours and 31 minutes. She landed her passengers before sunset on Thursday, Aug. 13, and lowered her own record by about 3½ hours. She encountered heavy fogs for several days.

◆

THE U. S. ARMORED CRUISER "BROOKLYN" will leave the Cramp ship building yard on Aug. 22 for her trial trip off the Massachusetts coast. The course is from Cape Ann to Cape Porpoise, a distance of 41.5 knots. The dimensions of the "Brooklyn" are as follows: Length on load water line, 400 ft. 6 ins.; extreme beam, 64 ft. 8¼ ins.; mean draft, 24 ft.; displacement, 9,271 tons. The four engines are of the twin screw vertical triple-expansion type, with 16,000 I. HP.; she has a normal coal supply of 900 tons and a bunker capacity of 1,753 tons. The contract speed is 20 knots; but 22 knots is expected in the trial. Her main battery contains eight 8-in. breech loading rifles and twelve 5-in. rapid-fire guns; the secondary battery includes twelve 6-pdr. and four 1-pdr. rapid-fire guns, and four Gatling guns. She has five torpedo-tubes, and the armor is 3 ins. thick on the sides, 5½ ins. on turrets and 8 ins. and 4 ins. on the barbettes, with 6-in. and 3-in. protection decks. The "Brooklyn" will carry 46 officers and 515 men, and the hull and machinery were contracted for at $2,986,000 and the keel was laid on Aug. 2, 1893. The ship is designed to have a radius of action of 1,758 knots at full speed and 6,088 knots at a speed of ten knots.

THE CAISSON ACCIDENT, in the Brooklyn Navy Yard, is still under investigation. Civil Engineer A. G. Menocal, U. S. N., in his testimony, gives his figures and reasons for assuming that it would be safe to entirely remove the stone ballast before substituting concrete. According to the published testimony Mr. Menocal estimates the water pressure against the caisson at about 740 tons, producing "a friction" on the rubber gasket, between the caisson and the dock of 370 tons. To this friction he added the weight of the caisson itself, which was 225 tons. The buoyancy of the caisson was 390 tons and he thus assumed a margin of safety, against lifting, of "over 200 tons," which he considered safe enough. Mr. Menocal charged the accident to the extreme heat, which tended to soften the rubber in contact with the heated plates of the caisson. Civil Engineer F. C. Prindle, U. S. N., testified that the removal of the ballast was the cause of the accident, and he could not think of any other cause; in his experience the total removal of the ballast was unprecedented in a similar operation. Judging from results alone, the slightly slower method of gradually replacing the stone by concrete would have been the safer method, and would have altogether avoided any reliance upon risky factors of frictional safety.

◆

A NICARAGUA CANAL, says the Panama "Star and Herald," is to be cut by the Nicaraguan government to connect Pearl Lagoon with Pine Lagoon, and give access to the first lagoon from Bluefields, through Pine Creek. The canal would be about three miles long, and Mr. Frank Field is named as the contractor.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week was a head collision Aug. 15 at Torch, W. Va., on the Baltimore & Ohio Southwestern Ry. An eastbound fast freight train had run past the place where it had orders to wait for a westbound express train, and the two trains collided. Both enginemen and the fireman of the express were killed, and three other trainmen were seriously injured.——A westbound express train on the Denver & Rio Grande R. R. was wrecked near Pueblo, Colo., Aug. 15, owing, it is thought, to distortion of the rails by the great heat. The engineman and fireman were killed and about 20 passengers slightly injured.——A passenger train on the Lake Shore & Michigan Southern Ry. was wrecked near Otis, Ind., Aug. 13 by the collapse of a culvert which had been washed out by a sudden storm. The engineman and fireman were killed.

◆

A HEAD COLLISION OF ELECTRIC CARS occurred on the Brunswick Traction Co., between New Brunswick and Milltown, N. J., Aug. 16. One car was trying to reach the next turnout beyond the one at which it should have waited for the other car.

◆

A BOILER EXPLOSION occurred Aug. 13 at the brick and tile works at Louisville, O., and two men were fatally injured.

◆

A STEAM ROLLER RAN AWAY on Glenmore Ave., New York city, recently, and went down a bank into a gully.

◆

A COLLISION BETWEEN LAKE STEAMERS occurred in the Lake St. Clair channel on the night of Aug. 14, and both vessels were sunk in 17 ft. of water, but nobody was killed. The vessels were the "Oceanica," 1,490 tons, with coal from Buffalo to Chicago, and the "William Chisholm," 1,581 tons, with ore from Marquette to Ohio ports.

◆

A HEAVY STORM in the neighborhood of Pittsburg, Pa., on Aug. 13, caused a flood in Pine Creek, and five persons were drowned at De Haven.

◆

A DYNAMITE EXPLOSION at New Holland, Pa., on Aug. 17, killed three men, injured seven others and caused considerable damage to property. The Pennsylvania Telephone Co. is rebuilding its line between New Holland and Lancaster, and uses dynamite in blasting out the post holes. The gang was preparing to start out to work and one man had gone into the shed to fetch the dynamite when the explosion occurred.

◆

AN INTEROCEANIC ROUTE is to be maintained by the National Railway of Tehuantepec, which has been leased by the Mexican government to Weetman, Pearson & Son, of London, for 50 years. This company, which has contracted for many large public works in Mexico, will improve the railway terminals and harbors at Coatzacoalcos on the Gulf and Salina Cruz on the Pacific.

◆

CONCRETE AND STEEL IN COMBINATION has been adopted with success on some of the sewers built by the Metropolitan Sewerage Commission of Boston. One of the main outlet sewers built by the commission at a point where it crossed private property in Mattapan came within 8 ins. of the surface, and at a time when the sewer was flowing very full the internal pressure became sufficient to break the arch of the sewer and flood the land adjacent to it. To prevent a recurrence of the accident Mr. Wm. M. Brown, Jr., Superintendent of the Metropolitan Sewerage Commission, purchased about 4,500 sq. ft. of expanded metal, bent this to the arch of the sewer and built a new 8-in. concrete roof, embedding the expanded metal in the concrete and placing it about 2 ins. from the outside of the arch. The expanded metal extended from the crown of the arch to the springing line on each side, and its strength is such that no fears are entertained as to the safety of the arch in future. We are informed that on other sections where similar trouble was experienced the sewer was entirely relocated and rebuilt at a lower grade for a considerable distance. The expense involved in this was, of course, far greater than in the simple repair with expanded metal described above.

◆

MAIL SERVICE BY ELECTRIC CARS has now been in operation in Brooklyn, N. Y., for two years, having been commenced on the Atlantic Ave. R. R. in August, 1894, the cars running between the general Post Office and Coney Island. The service gave satisfaction to the postal authorities, and it was not long before there was a demand for its extension to other parts of the city. The first step in that direction was in the transportation of mail pouches on the front platforms of cars, but later arrangements were made with the Brooklyn Heights R. R. Co. for the running of mail sorting cars over several of its lines. Of these cars there are now seven in regular operation, and by means of them a great saving of time in the distribution of mails is effected. The original electric mail service on the Atlantic Ave. R. R. is no longer maintained. The contract was not a liberal one from the company's point of view, being based on the amount of mail mater carried, estimated in pounds or tons, and the new management felt that the company was not getting enough out of it to make it worth while to continue the arrangement.

◆

A 30-STORY OFFICE BUILDING is to be erected on Park Row, New York city, on the site of the old International Hotel, and will be about 386 ft. high from the curb line. There will be 27 main floors and three floors in side towers, 30 in all. The foundations consist of piles driven into the sand, cut off below the water line and covered with the concrete and masonry bases for the columns. The outer walls will be carried by cantilevers, as in many other tall buildings of this character. The architect is Mr. R. H. Robertson, of New York city.

◆

HARD VS. SOFT WOOD FOR STREET PAVING has been considered by a special committee of the Paddington Vestry, London. In this parish the past practice has been to use soft wood with Portland cement joints. The surveyor of the parish reports that the life of this pavement is shorter than it was some years ago, owing to increased traffic, a higher standard of surface demanding more frequent repairs, and a decrease in the quality of the wood used owing to increased demand. The committee finds the present life of this soft wood under heavy traffic to be only six years, against 15 years for hard or jarrah wood pavement; and this committee finds a saving in cost in using the latter and recommends that all wood roads be renewed as soon as practicable with the best jarrah wood.

◆

DR. FRIDTHOF NANSEN, says a special despatch to the "St. James Gazette," has arrived at Vardoe, an island on the coast of Norway. According to the meagre reports current he left his specially-constructed ship, the "Fram," in March, 1895, and attempted to push towards the North Pole over the ice which his ship could not penetrate. Nansen claims to have attained latitude 86° 14′ N. This is 2° 50′ further north than the 83° 24½′ attained by Lockward and Brainard, of the Greely expedition in 1883. In 1891 Lieut. Peary reached latitude 83° 24′ N. From the point named some members of the expedition returned south to Franz Joseph Land and Dr. Nansen and Lieutenant Hansen reached Norway on the steamer "Windward," which had been conveying provisions to the Jackson-Harmsworth expedition. The "Fram" is supposed to be on her way to Vardoe or Bergen. Dr. Nansen sailed from Vardoe on July 21, 1893, intending to reach an alleged open sea north of the 82nd degree of latitude and to drift in the ice across the Pole. It may be stated that some of the reports concerning the manner of Dr. Nansen's undoubted return are contradictory, and nothing is known of the fate of his companions left on the "Fram."

THE BLOOMING DEPARTMENT OF THE TROY Steel Company was started for the first time on Aug. 8. This new plant was commenced in September, 1895, and the machinery was built by the Mackintosh-Hemphill Co., of Pittsburgh, Pa., from the plans of Chief Engineer Arnold, of the steel company. The plant includes a pair of 42 × 60-in. reversing engines and in full operation the output of finished steel will be 800 tons per day. In making Bessemer steel the vessels are lined with calcine dolomite, instead of silica, ground fine, mixed with gas-tar and pressed into bricks under 500 tons pressure. The entire plant is expected to be in operation in about a month, employing 1,200 men.

ORE HOISTING AND CONVEYING MACHINERY AT ASHTABULA, OHIO.

We illustrate herewith an ore hoisting and conveying apparatus designed and built by the King Bridge Co., of Cleveland, O., and located on the ore docks of the Pittsburg, Youngstown & Ashtabula Ry., at Ashtabula, O., operated by Messrs. M. A. Hanna & Co., a firm whose senior member is not unknown to fame. The King Bridge Co. has a wide reputation as a builder of bridges, but it has also built quite a number of conveying machines of the general class represented, the earliest having been built in 1882. The present design contains a number of improvements suggested by the company's experience.

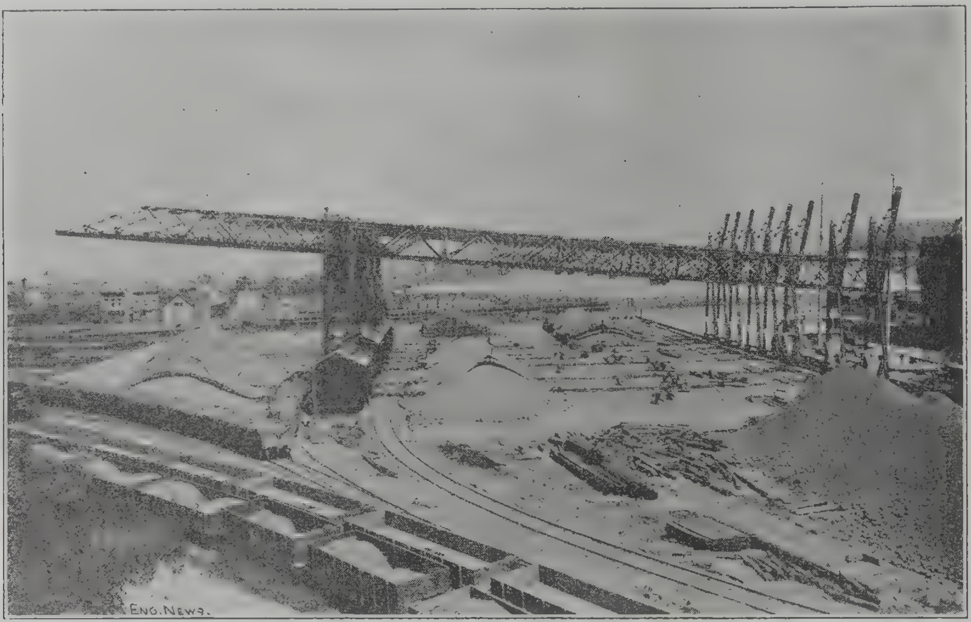

FIG. 1.--ORE-HANDLING MACHINERY ON PENNSYLVANIA CO.'S DOCKS AT ASHTABULA.
Designed and Built by the King Bridge Co., of Cleveland, O.
(Span between Towers, 180 ft.; Cantilever, 88 ft.; Apron in front, 34 ft.)

The structure, as now built, contains eight separate bridge trusses, each 180 ft. long, between the towers, with a cantilever 88 ft. long projecting over the rear tower and a folding apron 34 ft. long on the front tower, which can be raised and lowered so as not to interfere with the masts of vessels when they are taking position at the dock. The bridges are arranged in pairs, that is two of them have a common support in a tower at the rear, while there is a separate support or leg at the front for each bridge. The complete plant thus contains four towers at the rear and eight legs at the front. All of the towers and legs are supported by wheels on tracks consisting of two rails at the rear and one in the front. The moving of the plant from one point to another is done by steam or electric power applied to the wheels at the rear, and by hand gearing at the front.

The bridges are hinged to each side of the top of the rear tower and at the top of the front tower they are hung by means of adjustable connections. This mode of attachment allows the bridge or projecting apron, without being strained in the least, to be operated directly from the hatchway of a boat without moving the whole machine. There is a clear space under the bridges from top of the dock of about 30 ft., giving room for storage purposes, when it is not convenient to unload a vessel directly into the cars. The bridges are on a grade in order to increase the storage capacity of the dock.

The machinery is all operated from the engine room, where it is under the constant watch of the engineer. Outside of the engine room, on the bridge, there are only the sheaves and steel ropes.

The hoisting engines used on the plant described are of the Lidgerwood pattern, with reversing gear, and these, with the boilers, are placed in an engine room built in the rear tower. The rear tower is also propelled up and down its track on the dock by a gearing located in the engine house, from which power is furnished to raise and lower the apron at the front tower. The bridge is constructed with an upper and lower runway, the upper forming the track for the hoisting and the lower for the conveying carriage, from which are operated wire conveying ropes to which the buckets are attached. The hoisting drums can be so operated that the bucket is hoisted and conveyed at the same time, taking the shortest line between two points, and be stopped at any height and place. It does not need to be hoisted into contact with the carriage before the conveying takes place and it requires no latch mechanism, such as is usually employed in machinery of this description.

When the plant is completed with ten legs it will have more than ample capacity to unload the ore boats of the most recent design, which have 12 hatches and measure 432 ft. in length over all, with a capacity of 6,680 net tons of ore on 19 ft. draft.

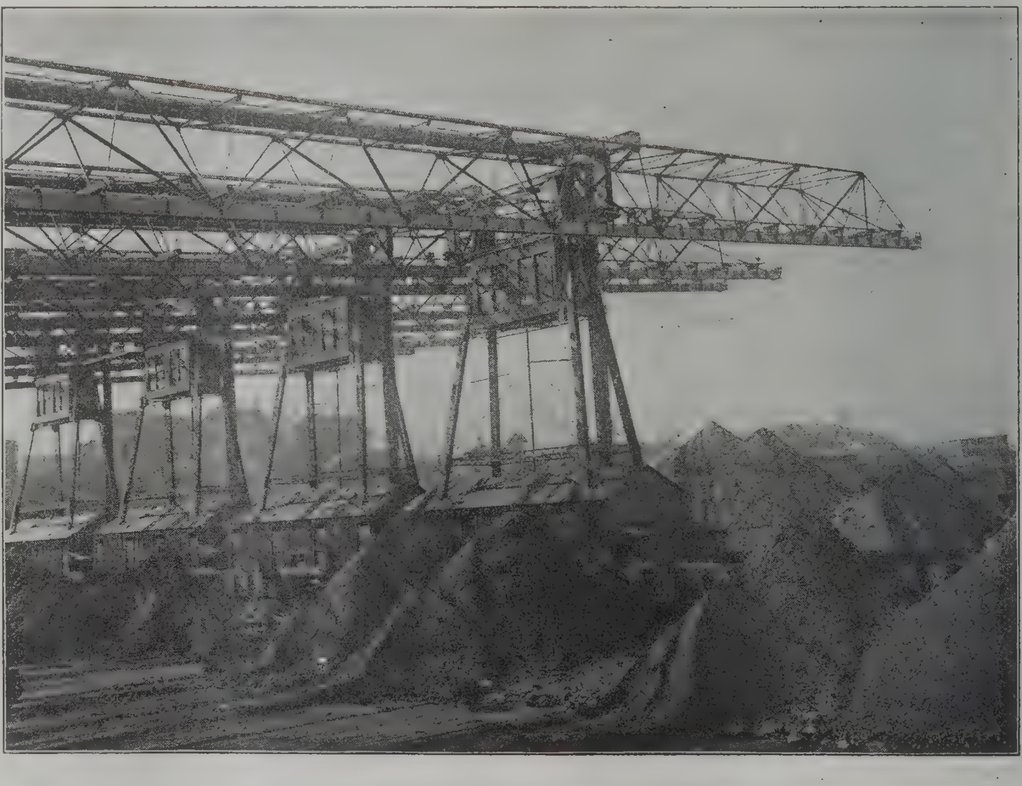

FIG. 2.--VIEW OF REAR TOWERS AND OPERATING HOUSES.

Concerning the actual operation of the plant as now built, with eight legs, Mr. Geo. B. Raser, the manager of the dock at Ashtabula, says, that on Sept. 26, 1895, the steamer "Roman," with 2,500 tons of ore, commenced unloading in cars at 6.30 a. m. and finished at 5.30 p. m.; and on Sept. 28, 1895, the steamer "German," with 2,540 tons of ore, commenced unloading in pile at 7 a. m. and finished at 5.30 p. m. An allowance in each case should be made for shut-down of one hour at noon, and in neither of these cases was any special effort made to obtain a record or special good showing. These boats were unloaded into cars standing on the two tracks near the water front, and not into the pile, and there is always a loss of from 30 to 50% of time occasioned in pulling out the loaded cars and replacing them with empties. The time thus lost it is the intention to save by laying two additional tracks for cars, besides the two now used, so that two cars may be placed under each hoist at the same time. One of these cars may be loaded while the other one, being full, is being replaced by an empty.

The general arrangement of machinery, mode of operation and important details and safety devices are all covered by the Rasch and other patents controlled by the King Bridge Co. The company intends hereafter to operate this branch of its business extensively. It is also at present engaged in perfecting a coal handling device for unloading cars directly into boats.

TRACK ELEVATION, CHICAGO & NORTHWESTERN RY., IN CHICAGO.

(With inset.)

The only railway company now prosecuting the work of track elevation in Chicago is the Chicago & Northwestern, which has about 3.6 miles of its Milwaukee Division undergoing this improvement. In previous issues* this journal has outlined and discussed the scope and progress of the work of abolishing grade crossings which the great western metropolis has undertaken, and where conditions permitted a definite statement the structural details of the work have been described. Compared with the task as a whole the progress thus far made seems small, but it is great in its promises of future results. Opposition and delay on the part of several of the railways entering the city will doubtless continue, but the larger number show a disposition to consider the question broadly and fairly and to meet the city half way in its efforts to solve a pressing and difficult problem. Among this larger number the Chicago & Northwestern Ry. Co. is notable for having taken up the work with good will and energy. This company has already elevated 1.85 miles of its line, is now at work on an additional 3.6 miles, and has contract to elevate another section of its line in the near future. In the following paragraphs the work of the Chicago & Northwestern Ry. is

described as completely as its present progress and available information will allow.

The Chicago & Northwestern Ry. system radiates west and north from Chicago in three main lines from the passenger station at Wells St. and Fifth Ave., just north of the main branch of the Chicago River. From the Wells St. station the Galena Division or line extends almost directly west. The other two lines have a common right of way northwest from Wells St. station to Clybourne Junction, about three miles, and then separate, one line going north to Milwaukee and thence to northern Wisconsin and Michigan, and the other northwest to St. Paul and Minneapolis. For sake of brevity in the following description these lines will be designated as the Galena, Milwaukee and Wisconsin lines, respectively.

The first work of track elevation done by the Chicago & Northwestern Co. was on the Galena line, and comprised the raising of about 1.85 miles of five-track railway, the construction of six new subways for crossing streets, and the remodeling of a seventh subway. The general character of the subway constructions, except that at Sacramento Ave., which was built in 1893 (Eng. News, Sept. 21, 1893), and is only remodeled in the present construction, is shown by the accompanying table:

Name of street.	Elevation, track.	Depression, street	Length, floor.	Length, inclines.	No. tracks, bridge.	Span of bridge.	No. of spans.
	ft.	ft.	ft.	ft.		ft.	
Kedzie Ave...... ..	10.69	3.82	130	110	5	66	1
Homan Ave	11.3	3.5	149.7	100	5	66	1
St. Louis Ave	11.59	3.18	150	91	5	50	1
Central Park Blvard..	11.16	2.34	120	115	5	92	2
Hamlin Ave	11.3	3.22	120	92	5	80	3
W. 40th St...........	8.5	6.1	306	175	9	66	3

Note.—The grade of all inclines is 3.5%. The names ot some of these streets have been changed since the work was begun. At Sacramento Ave. the roof of the subway was raised 3½ ft. and its floor a corresponding distance.

It will be seen that the work naturally divided itself into two processes: (1) The construction of the subways at street intersections, and (2) the elevation of the tracks between the cross streets. As the subway construction can be better described later on it will be left for the present and attention turned to the elevation between streets. This was simply earth embankment work; and according to the terms of the ordinance signed with the city, retaining walls were to be built wherever necessary to keep the embankment within the limits of the company's right of way. This right of way is only 100 ft. wide, and with only five tracks retaining wall was needed only along a part of the distance, but some time in the future when other tracks are added the wall will be extended as needed. These walls were built of limestone masonry with a concrete footing and present no features out of the ordinary.

Probably the most interesting part of the embankment work was the method of filling adopted. Fig. 1 shows this method quite clearly. The bottom solid line shows the original grade of the tracks and the top solid line the grade after elevation. The broken lines show the different sections of the embankment numbered in the order they were built. For example, triangles No. 1 were first built with sand hauled by train, the tracks being raised little by little until they conformed to the grade indicated by the line A, B, C, D, E. It will be noticed that the tracks crossing Kedzie Ave., at C, had not been elevated thus far, but now the girders for the two outside and the center tracks, with floor system, tracks, etc., complete, were brought to Kedzie Ave. mounted on jacks on flat cars, and were hoisted onto temporary pile abutments, but not up to full grade. Two tracks, it will be noticed, were unobstructed by this work. The girders being hoisted to their temporary positions, triangles 2, 2 were filled in, which as the quantity was small, was done in one day. The tracks now followed the grade A, B, F, D, E, and the trains run over the two outside tracks and the center track. The bridges for the remaining two of the five tracks were then raised onto their temporary abutments. Everything was now ready for filling the irregular prism 3, raising the bridges to full grade, and the girder erection at Homan Ave., after which triangles 4 and 5 were filled, and so on west until the work was completed.

This method was new with this work so far as we know, and proved decidedly efficient. Only one street was closed at a time, the grade was never greater than 1%, and not more than 1,500 ft. of track was unsurfaced at one time. In the elevation now in progress on the Milwaukee line practically the same method of filling is being used, except that as there are here only three tracks the fill for each track is brought to its full height before the track is swung to one side and up onto it. This means that all three tracks are swung a distance equal to the distance between centers of tracks to one side.

Attention will now be turned to the track elevation on the Milwaukee line which is in progress. Altogether there are 3.6 miles of three-track line to be elevated, comprising the construction of 20 subways and about 300,000 cu. yds. of fill. Not all of this work will be done this season, however; only 12 subways and about 153,000 cu. yds. of filling being now contemplated. The general method of embankment construction has already been described, and need not be mentioned further.

Out of the total 20 bridges to be constructed across intersecting streets, 13 will have spans of 66 ft., five spans of 80 ft., one a span of 100 ft. and one a skew span of 139 ft. These last two spans will be included in the work now under construction, but all the other bridges built this year will have spans of 66 ft. Generally the streets will be depressed from 2 ft. to 4.5 ft., only five being changed more or less than these amounts. The track will be elevated about 9 ft. above its present grade and the clearance of the subways will be generally 10 ft. or 12 ft., only two structures having a greater clearance, 13.5 ft. All 66-ft. streets are to be crossed by a single span, but two or more spans will be used for streets of greater width.

For the purpose of illustration one of the 66-ft. bridges will be used, as the others differ from them only in size. The city ordinance required simply that the bridges have iron or steel girders, watertight floors, and masonry or masonry and metal column foundations. This is essentially the construction adopted. Fig. 2 shows the girder and floor construction in detail, and Fig. 3 gives an enlarged detail of the track construction particularly is noticeable. The floor beams consist of two channels riveted back to back with a filler plate between, extending to within about 1 ft. of the beam ends. These beams are fastened to gusset plates, which slip into the spaces left by the filler plate at each end of the beam, and are spaced 5 ft. c. to c. The stringers consist of two 6 x 16 ins. oak timbers carried in a trough formed by two Z-bars and a plate, and riveted to the floor beams. Between the oak stringers the space is covered with 3-16-in. deck plate which closes the floor solid and prevents dripping of dirt or water onto the subway floor beneath.

It will be seen that there are several advantageous features to this floor. It has a small depth, gives an even distribution of the wheel loads, is very simple to construct and erect, and is not of excessive weight, 540 lbs. per ft., in proportion to its supporting strength. The wooden stringer gives an elastic rail bed and tends to reduce noise. To this latter condition the division of the floor plates into comparatively small sections also contributes. The designer of this floor was Mr. Louis H. Evans, M. Am. Soc. C. E., Engineer of Track Elevation, Chicago & Northwestern Ry.

The design of the subway bridges having been explained attention may be turned to the method of erecting them. From the shops of the Lassig Bridge Works, Chicago, the builders, the various parts are shipped assembled in convenient sections to the erecting yard of the railway company. Here is located the erecting frame shown by Fig. 4, by means of which the two girders and floor system for one track are erected complete. Blocked up on two flat cars, the structure weighing 70 tons, about, is conveyed to the bridge site, where everything has previously been put in readiness for its reception.

At the bridge site the first work is to excavate under the tracks, keeping them all the time blocked up to carry the traffic, and then to build the concrete foundations for the abutments. There being three tracks, piles are then driven at each side of the proposed line of one of the side tracks and at each end of the bridge site, which will serve as temporary abutments. As shown by Fig. 5 the flat cars carrying the bridge for this track are backed onto the site; the bridge raised off them by screw jacks and blocked up on the piles; and finally the cars pulled from under. It will also be noticed from the illustration that the embankment has been brought up to the bridge site in the direction of progress and is held by a timber bulkhead. As soon as the cars are withdrawn a similar bulkhead is built at the end opposite the first and the filling begins so that the track may be carried over the bridge and onward. By the method of filling before described, it requires only a few trainloads of dirt to accomplish this end. Inside the timber bulkheads the masonry abutment work is also progressing.

The bridge for the other outside track, consisting of two girders and a floor system, is placed in exactly the same manner as the first. There remains then only the work of putting in the floor system for the center track, which is done on the bridge site, as clearly shown by Fig. 6. The completion of the abutments, the leveling and testing of the bridge, and the depression of the street now remains.

Fig. 7 is a view of one of the bridges with the abutments nearly completed and the street depression in progress. As the abutment foundations are completed before the bridge is placed, there only remains the masonry walls to be built. An I-beam is attached to the bottom of the bridge, so as to extend transversely across it about over the line of the facing course of masonry. On this runs a trolley which carries a pulley hoist, for handling the stone. The stones are brought to the site on cars and unloaded by a wrecking crane. From the stone pile a fixed derrick supplies the stone to the trolley hoist.

The street depression is simple excavation, about the only difficulties encountered being the occasional changing of water and sewer pipes. It is required by the ordinance that the grade of the approaches shall be 3½%, and that the width of roadway and sidewalks shall remain unchanged. The approaches are to be paved as was the original street, but the subway floor proper is to have a vitrified brick pavement laid on ½-in. of sand on a 6-in concrete foundation. Drainage is to be provided for by suitable catch basins and connections with the sewer.

In the foregoing, reference has been had to single span 66-ft. subways only, and as already stated the work comprises one 100-ft. span and one 149-ft. skew span subway. Fig. 8 shows the bridge for the 100-ft. span subway, and explains clearly the center column support and the apparatus used in the masonry construction. The 149-ft. subway is located where Lincoln Ave. joins Addison St., at an angle, and its outside or longest bridge girder is 235 ft. As indicating the rapidity of work, the bridge (one track), of which this girder is a part, was erected ready for traffic in five hours from the time it left the erecting frame in the yards. The regular rate of progress for 66-ft. bridges is seven single-track bridges erected in six days. About 3,000 cu. yds. of sand are hauled by train and put into the embankment each day and the contractors for street depression add to this about 1,000 cu. yds. per day. This makes the rate of progress 6,500 lin. ft. per month of three-track, 66-ft. right of way elevated 9 ft.

Altogether the work now in progress on the Milwaukee line will cost about $1,000,000, and as will be inferred from the foregoing it is entirely north of Clybourne Junction, where the Wisconsin and Milwaukee lines join to enter the city station. In the same manner the elevation of the Wisconsin line will begin north of Clybourne Junction and extend north, unaffecting the common line from the Junction south. No work has been done on this line, but the ordinance providing for its elevation has been passed by the Chicago City Council, and the construction it requires is in all respects similar to that just described. There will be 26 subways, including one subway for pedestrian travel only. Of this number 18 will have bridges of 66-ft. span, five bridges of 80-ft. span, one a bridge of 73-ft. span, one a bridge of 100-ft. span, and one, the foot subway, a bridge of 10-ft. span. The length of line to be elevated will be 4.6 miles. It is not definitely known when work will begin on this line, as the ordinance requires simply that it shall be completed within eight years, but the policy of the railway company seems to be to get the work accomplished as soon as practicable and it is entirely possible that the summer of 1897 will see it begun.

For the information from which this article has been prepared we are indebted to Mr. Louis H. Evans, M. Am. Soc. C. E., Engineer of Track Elevation, Chicago & Northwestern Ry.

◆

TEST OF WATER-BEARING GRAVEL AT BEAVER FALLS, PA.

An interesting test to determine the quantity and quality of water that could be obtained from water bearing gravel, at Beaver Falls, Pa., was conducted in 1894, by Jas. H. Harlow & Co., of Pittsburg. The gravel in question overlies a blue silt, practically impervious to water, which, in turn, overlies sandstone rock, about 40 ft. below the surface, and was located at the junction of Wallace Run and the Beaver River. The test showed that a sufficient quantity of water for a small water-works plant could be secured but that a large part of the water came from the river, which is polluted with sewage and likely to become more so.

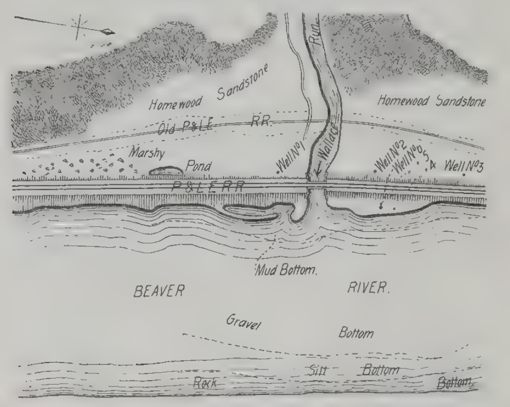

Fig. 1.—Plan Showing Location of Test Wells at Beaver Falls, Pa.

James H. Harlow & Co., Pittsburg, Engineers; Simon Harrold, Beaver Falls, Contractor.

The following particulars regarding the test are taken from the report on the subject, made by the engineers to the officials at Beaver Falls.

The site chosen for the test was selected in accordance with the best data available, and in accordance with a belief that the gravel stratum overlying the rock was exposed at the surface of the bed of Beaver River.

The two streams, Wallace Run and Beaver River, are described in the report as follows:

> Wallace Run enters the Beaver River from the west, and and drains about three square miles of farming country. The stream descends rapidly from its source and flows over a broken surface of soil and rock. At the mouth of the Run no water has been visible for the past month and if any water is passing down the Run it is below the surface.
>
> The Beaver River, above the mouth of Wallace Run, has a drainage area of 2,964 sq. miles, about 1,600 miles of this being within the state of Ohio. Within this drainage area we have, as per census reports of 1890, 255,732 population, an average of 86.3 per sq. mile. This population has undoubtedly increased within the four years that have elapsed since 1890, and by 1900, if the increase in population be the same as the last decade, we may expect at least 300,000 population. During the decade of 1880 to 1890 nearly all of the increase within the drainage area of the Beaver River was within the following cities and villages, viz.: Newcastle, Pa.; Greenville, Pa.; Butler, Pa.; Sharon, Pa.; Youngstown, O.; Niles, O.; Warren.
>
> The average increase of the above places for the past decade was 70%, and we may expect a similar increase for the present decade, or in 1900, when these places will probably have a population of at least 130,000.

The tests for capacity were conducted under the supervision of Mr. H. F. Labelle, Principal Assistant to Jas. H. Harlow & Co. The plans, as carried out, provided for the sinking of four wells to rock and of a fifth well, 8 ins. in diameter, at such a point in relation to the others as should finally be deemed best for the pumping trial. The specifications for the pumping test provided for 20 days continuous pumping and stated that:

> If for any reason caused by defective machinery or negligence of the contractors or their employees the pump shall be stopped at any time for a period exceeding one-half hour, it shall be optional with the engineer to begin a new test, and no payment shall be made for any pumping that may have been done previous to the beginning of this new test.

The test was to be made with a pump having a capacity of not less than 250 gallons per min., or 360,000 gallons a day.

The arrangement for measuring the pumpage from the wells is described in the report as follows:

> The pump was to discharge into a measuring flume at one end of which was a weir similar to that used by Francis and others. This flume was 16 ft. long, 3.71 ft. wide, 1.75 ft. deep, inside dimensions. The weir was placed 1.29 ft. above the bottom of the flume and had a length of 1.005 ft. Across the bottom of the flume and 2 ft. from the weir was placed a ¾-in. pipe plugged on the end inside the flume, and the open end extending through the side of the flume into a gage box. In this pipe were drilled several ⅛-in. holes to admit the water and show the depth on the weir. In the gage box was fastened a glass tube which was connected to the open end of the ¾-in. pipe by gum tubing. The zero of the glass gage coincided with the weir, and by noting the height of the water in the glass gage the depth of the water on the weir was ascertained. In the gage box was placed, in addition to the glass gage, which was read direct, a Bristol's recording gage. This gage makes its own record on the circular card which was rotated once in 24 hours by clock work. The records for this gage were failures, and have not been given in the accompanying tables. The object of this recording gage was to show if any stoppages occurred during the absence of the assistant, and to give the time such stoppages did occur. The gage did show when the pump stopped, but not accurately the depth on the weir and the only advantage gained by its use was its moral effect on the man in charge of the pump, as he did not know of its inaccuracy.
>
> The water from the well enters the opposite end of the flume from the weir, and of course entered with considerable force. To make the water approach the weir uniformly and quietly there were placed across the flume three wire screens of ⅛-in. mesh.

After advertising for bids the contract for sinking the wells and making the pumping test was awarded to Mr. Simon Harrold, of Beaver Falls. The first well was begun on June 11, and the five wells were completed about July 1. The wells are shown in plan by Fig. 1, and in section by Fig. 2. The stratification at the first four wells is indicated by the sections, Fig. 2, the elevations being heights above sea level. The depth of each stratum for the various wells are extracted from the reports, slightly condensed, as follows:

> No. 1.—2.5 ft. of vegetable ground; 6 ft. yellow loam; 5.6 ft. fine sand with some water; 7.4 ft. coarse sand and fine gravel; 17.3 ft. blue silt, this silt lying on sandstone rock, which is yellow in color; total depth, 38.8 ft.
>
> On June 13 the water stood in well No. 1 at elevation 735.23, the water in the river being 735.01, showing water was 0.22 ft. above that in the river.
>
> No. 2.—2 ft. of vegetable ground; 4.8 ft. loam and stones, some gravel, water put into casing disappearing immediately; 8.7 ft. sand, without much gravel, water bearing; 7.1 ft. of coarse sand and small gravel; 18.4 ft. blue silt similar to No. 1; 3.5 ft. fine gravel to rock, light gray in color; total depth, 42.5 ft.
>
> No. 3.—21 ft. of sandy loam, with the sand increasing gradually downward; 1 ft. sand and gravel; 8.7 ft. sandy loam, merging into gray silt at the bottom, where light gray sand and rock was found; total depth, 30.7 ft. The casing of this well was afterwards withdrawn.
>
> No. 4.—6 ft. of sandy loam; 10 ft. sand and gravel; 43.5 ft. blue silt similar to Nos. 1 and 2, merging into blue clay, with a little gravel at the bottom of the well. This silt overlies a sand rock light gray in color.

Well No. 5 was sunk to within 2 ft. of the top of the flue silt. It showed practically the same stratafication as well No. 4. The well was 8 ins. in diameter, cased, the lower 5 ft. of the casing being pierced with 1,400 holes, each 3-16 ins. in diameter, and the extreme end of the casing being roughly plugged with stone to prevent the admission of sand.

Owing to trouble with the pumping plant the contractor did not start his 20-days run until July 25.

The weir discharges were computed by the Francis formula,

$$Q = 3.33\, H^{\frac{3}{2}}\, L,$$

with corrections for end contraction and velocity of approach.

The detailed results of the capacity test are given in tables accompanying the test. The yield decreased from some 340,000 gallons per 24 hours for the first two or three days, to 215,000 gallons at the end of the test.

The report states that with a 5-ft. head the quantity of water that could be depended on within a radius of 175 ft. from the pumping well, which was the range of influence of the pumps, would be about 260,000 gallons a day. The conclusion is reached that

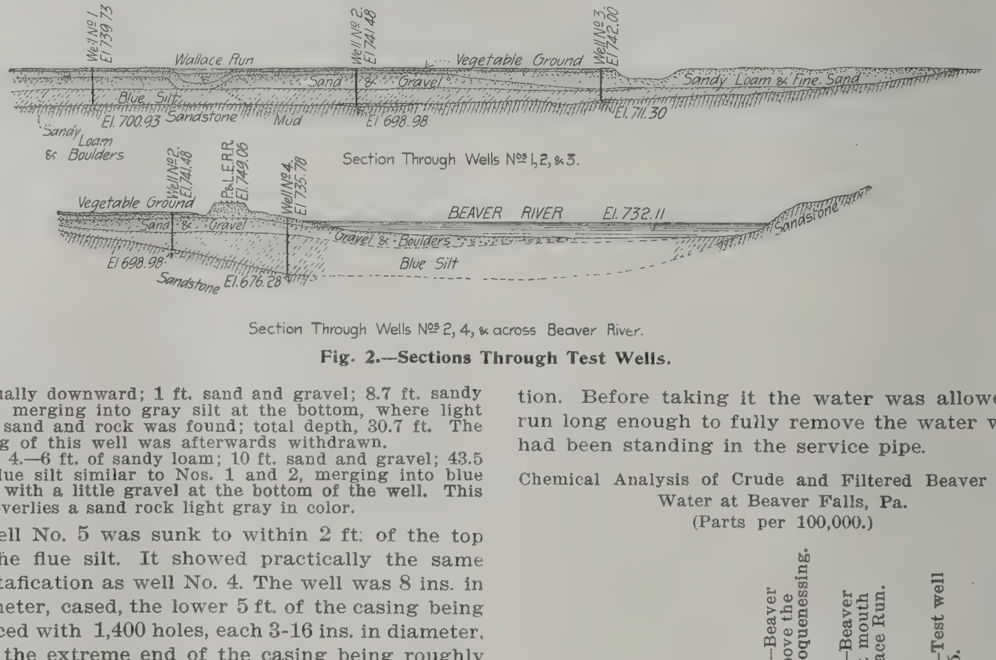
> it is probable a number of wells can be distributed along the bank of the Beaver River and into this same sand and gravel bed, and almost any quantity of water obtained, at least as long as the river lasts.

No comments are made regarding the effect of pumping on well No. 3. As to No. 1, the report expresses the belief that it "had no direct connection with the sand strata pumped from," water in this well usually standing above that in the river.

Wells Nos. 2 and 4 generally rose and fell with river, if the pumping was continued at a uniform rate. On one day the river rose at the rate of 0.1 ft. in eight hours, and the water in wells Nos. 2 and 4 about 0.08 ft. in the same time, the rate of pumping meanwhile increasing about 10,000 gallons an hour.

Another confirmation of the connection of the wells with the river was the temperature observations. When pumping was begun, the temperature of the water in well No 5 was 57° F., and in the river 76°, a difference of 19°. When pumping was stopped, on Aug. 14, the well water had a temperature of 71° and the river water 77°, a difference of only 6°.

Passing from the quantity to the quality of the supply, the report gives the results of chemical tests made by Mr. Jas. O. Handy, Chemist of the Pittsburg Testing Laboratory. These are reproduced in the accompanying table. Sample No. 1 was selected as indicating the character of the river before being affected by the salt wells on the Connoquenessing, and by the sewage of Butler, Pa. It was tested for chlorine, only, which seems unfortunate, since a test for organic matter would have aided in judging how much of the increase in chlorine was due to sewage contamination. Sample 3, from the test well, was taken from the discharge pipe of the pump. Sample 4 was selected as representing the character of the water being supplied to the borough by the water company at the time of the test. It was supposed to have passed through Hyatt filters at the pumping station. Before taking it the water was allowed to run long enough to fully remove the water which had been standing in the service pipe.



Section Through Wells Nos 2, 4, & across Beaver River.

Fig. 2.—Sections Through Test Wells.

Chemical Analysis of Crude and Filtered Beaver River Water at Beaver Falls, Pa.
(Parts per 100,000.)

	No. 1.—Beaver R. above the Connoquenessing.	No. 2.—Beaver R. at mouth Wallace Run.	No. 3.—Test well No. 5.	No. 4.—Faucet in Todd's drug store, Beaver Falls, Pa.
Albuminoid ammonia		0.0208	0.0138	0.0220
Free ammonia		0.0192	0.0266	0.0032
Nitrites		small	high	high
Nitrates		none	trace	trace
Chlorine	2.68	11.42	8.98	12.57
Sulphate of lime	6.80	6.82	6.02	6.31
Carbonate of lime	4.53	4.53	4.85	4.51
Sulphate of magnesia		1.07	0.00	1.19
Carbonate of magnesia		0.98	0.50	0.91
Chloride of magnesia		2.03	3.28	2.14
Sodium chloride		18.35	14.81	18.11
Sodium carbonate		6.38	1.91	9.45
Silica		0.26	0.40	0.28
Oxide of iron and alumina		0.28	0.00	0.20
Total		40.70	31.77	43.10
Hardness		14.40	13.90	14.22

The engineers' comment upon the analysis is as follows:

Chlorine.—Chlorine in No. 1 is an indication of probable sewage from the towns above the Connoquenessing, but in samples Nos. 2, 3 and 4 the chlorine represents largely the salt, which is known to come from wells on the Connoquenessing. Sample No. 4 has the largest amount, and it is possible the difference between it and No. 2 is due to sewage entering below Wallace Run. Sample No. 3 has the lowest of any below the Connoquenessing, and this difference is probably due to the admixture of ground water into well No. 5 from the sandstone hillside. We think in this instance there is no special difference in the several waters, if the high amounts show an excess of salt, which is harmless.

If we can assume that there was but little chlorine in the water that came from the sandstone, we may estimate from the amount of chlorine in samples Nos. 2 and 3, that 90% of the water pumped was from the river, and 10% from the hillside. We are inclined to think, however, that more than 90% of this water comes from the river.

Ammonias.—As the figures stand, sample No. 3, as shown by the albuminoid ammonia, is the best. If the water is largely river water (No. 2) it shows that it has been oxidized in passing through the sand. If there is a considerable amount of land water, as indicated by the chlorine, this lower amount may mean dilution only.

The albuminoid ammonia in sample No. 3, taken in connection with the free ammonia and high nitrites, would seem to show that the organic matter had been partially filtered or to a considerable extent oxidized, but that the oxidation was still going on, and is incomplete.

Sample No. 4 seems to be substantially the same water as sample No. 2, the albuminoid ammonia being practically the same. The low free ammonia and nitrites would seem to show that decomposition by oxidation had not yet begun, or at least carried to any great extent. The low amount of free ammonia may be accounted for (as it is a gas) by having been agitated in some manner, possibly by passing through pumps. The sum of ammonias is the sum of the decomposing and decomposed organic matter which may be either animal or vegetable. The former decomposes with much more rapidity than the latter, and contains much more nitrogen. In the case of sample No. 2, from the Beaver, which flows generally in a rapid stream, and at the time of the year when the streams are low and vegetation active, and considering that within the drainage of the Beaver are several large towns each of which have sewerage systems discharging into the river, we may conclude that the large amount of ammonia is an indication of sewage contamination. In a water at Lawrence, Mass., that was polluted to such an extent as to cause a great deal of sickness, 0.0037 free ammonia, and 0.0158 albuminoid ammonia was found, the sum of the ammonias being 0.0195. This is much lower than any samples that we have.

Lime.—The sulphate and carbonate of lime both cause scale in boilers and from a manufacturing standpoint should be gotten rid of. To a city largely given to manufacturing, it is important that these should be disposed of, even if at considerable expense. The sulphate of lime deposits a hard scale that has to be removed by the use of considerable force. The carbonate of lime deposits a soft scale that can usually be blown off with the water and steam, if this is done often enough. Samples Nos. 3 and 4 are practically the same in this respect.

Sodium Chloride.—This is common salt, and the quantity shown here is not noticeable to the taste and is not harmful.

Sodium Carbonate.—This is known in commerce as soda-ash and is used in making soap and glass. It has a tendency to neutralize the lime and soften the water. Nos. 3 and 4 are practically the same as far as relates to these substances.

Bacterial examinations of water from four sources were made by Dr. E. G. Matson, Professor of Pathology in the Western Pennsylvania Medical College, Pittsburg, Pa., with the following results:

Sample No.	Source.	Bacteria per cu. cm.
1.	Beaver River at Wallace Run	892
2.	Test well No. 5	874
3.	Test well No. 2	327
4.	Faucet in Todd's drug store, Beaver Falls	475

Samples Nos. 1, 2 and 4 correspond, respectively, with samples Nos. 2, 3 and 4 of the chemical tests. The water from the river and main well (No. 5) contain what Dr. Matson regards as a suspiciously high number of bacteria, and there is no material reduction of bacteria in the passage of the water from the river through the gravel to the well. Sample No. 3 is also condemned as being river water insufficiently filtered in its passage through the gravel. The number of bacteria in the city water does not reflect with certainty the efficiency of the filters, as the relation between the crude and filtered samples is uncertain and there may have been bacterial changes in the water while passing through the pipes.

The final conclusions drawn by the engineers from the pumpage, chemical and bacterial tests, and such surveys, borings and river soundings as were made, are as follows:

(1) That the water from the test well at the mouth of Wallace Run is clear and limpid so far as can be discovered by the naked eye.

(2) That the water obtained from the sand strata at the mouth of Wallace Run is mainly from the Beaver River. This is shown by the physical, chemical, and bacteriological examinations.

(3) That the quantity of water obtainable from the sand strata at the mouth of Wallace Run and above is practically limited only to the quantity flowing in the Beaver River, and the possibility of the surface of the gravel being covered with an impervious deposit brought down during floods.

(4) That the water in the Beaver River is contaminated by sewage from the towns above, and to an extent that is dangerous.

(5) That the water now delivered to your citizens is substantially Beaver River water, and that its quality might be improved upon.

(6) That if no other supply of water can be found other than the Beaver River, Wallace Run is a proper location for the works, and by a properly designed system of filtration the water can be purified of its sewage and lime, so that it will be fit for domestic and manufacturing purposes.

(7) The sand strata would clarify the water so as to make considerable less work for the filter, and reduce the cost of operation.

We would, however, advise some other source of a water supply if it can be found.

PAST AND PRESENT TENDENCIES IN ENGINEERING EDUCATION.*

By Mansfield Merriman, M. Am. Soc. C. E.**

The present status of engineering education in the United States is the result of a rapid evolution which has occurred in consequence of changes of opinion as to the aims and methods of education in general. These changes of opinion, whether on the part of the public or on the part of educators, together with the resulting practice, may be called tendencies. All progress that has occurred is due to the pressure of such views or tendencies; hence a brief retrospect of the past and contemplation of the present may be of assistance in helping us to decide upon the most advantageous plans for the future.

Thirty years ago public opinion looked with distrust upon technical education. Its scientific basis and utilitarian aims were regarded as on a far lower plane than the well-tried methods of that venerable classical education whose purpose was to discipline and polish the mind. What wonderful changes of opinion have resulted, how the engineering education has increased and flourished, how it has influenced the old methods, and how it has gained a high place in public estimation, are well known to all. The formation of this society in 1893, its remarkable growth, and the profitable discussions contained in the three volumes of its transactions, show clearly that technical education constitutes one of the important mental and material lines of progress of the nineteenth century.

Engineering courses of study a quarter of a century ago were scientific rather than technical. It was recognized that the principles and facts of science were likely to be useful in the everyday work of life and particularly in the design and construction of machinery and structures. Hence mathematics was taught more thoroughly and with greater regard to practical applications, chemistry and physics were exemplified by laboratory work, drawing was introduced, and surveying was taught by actual field practice. Although engineering practice was rarely discussed in those early schools, and although questions of economic construction were but seldom brought to the attention of students, yet the scientific spirit that prevailed was most praiseworthy and its influence has been far reaching.

This scientific education notably differed from the old classical education in two important respects: first, the principles of science were regarded as principles of truth whose study was ennobling because it attempted to solve the mystery of the universe; and second, the laws of the forces of nature were recognized as important to be understood in order to advance the prosperity and happiness of man. The former point of view led to the introduction of experimental work, it being recognized that the truth of nature's laws could be verified by experience alone; the latter point of view led to the application of these laws in industrial and technical experimentation. Gradually the latter tendency became far stronger than the former and thus the scientific school developed into the engineering college.

The very great value of laboratory experiments, and of all the so-called practical work of the engineering school of to-day, is granted by all. Principles and laws which otherwise may be but indistinct mental propositions are by experimentation rendered realities of nature. The student thus discovers and sees the laws of mechanics, and is inspired with the true scientific spirit of investigation. It should not, however, be forgotten that if such practical work be carried beyond the extent necessary to illustrate principles, it may become a source of danger. The student of average ability may pass a pleasant hour in using apparatus to perform experiments which have been carefully laid out for him, and yet gain therefrom little mental advantage. Especially is this true when the work assumes the form of manual training which, however useful in itself, is properly considered by many as of too little value to occupy a place in the curriculum of an engineering college.

The tendency toward the multiplication of engineering courses of study has been a strong one, especially on the part of the public. This has resulted in a specialization that, as a rule, has not been of the highest advantage to students. In some institutions this has gone so far that the student of civil engineering learns nothing of boilers and machines, while the student of mechanical engineering learns nothing of surveying or bridges. The graduate is thus too often apt to lack that broad foundation upon which alone he can hope to build a successful career.

The development of the scientific school into the engineering college has been characterized throughout by one element of the happiest nature, that of hard work and thoroughness of study. The numerous topics to be covered in a limited time, their close inter-relation, and the utilitarian point of view, have required many hours per week and earnest work by each student in preparation for each exercise. The discipline of hard and thorough work is one whose influence can scarcely be overestimated as a training for the duties of life, and in every university it is found that the activity and earnestness of the engineering students is a source of constant stimulus to those of other departments. Thus scientific and engineering education has tended to elevate the standard and improve the methods of all educational work.

The length of the course of study in engineering colleges has generally been four years, and whatever tendencies have existed towards a five-years' course have now for the most part disappeared. With higher requirements for admission, particularly in English and in modern languages, a reduction of the length of the course to three years may possibly be ventured in the future, particularly if the long summer vacation be utilized for some of the practical work, as indeed is now the case in several institutions.

There has been and now is a strong tendency toward a reduction in the length of the college year. While formerly forty or forty-two weeks were regarded as essential, the process has gone on until now some colleges have but thirty or thirty-two weeks, a reduction of nearly twenty-five per cent. having been effected in twenty-five years. Undoubtedly the long vacation is utilized to great advantage by the majority of students in actual work, yet the fact remains that it is not good business economy to allow the buildings and plant of a college to lie idle for so large a part of the year. It is perhaps possible that in the future the summer schools may be so developed that the work will be practically continuous throughout the year, thus giving to students the option of completing the course either in three or four years.

The report of the committee on requirements for admission, which will be presented later in the session, sets forth many facts which show the tendencies now existing. Almost without exception a higher standard is demanded, both that students may enter with better mental training, and that more time may be available in the course for technical subjects. While the general line of advance is toward an increase in mathematics and in modern languages, there is also found, particularly in the central states, a demand for broader training in science. It has already been pointed out that our early engineering schools were strong in scientific training, and that the tendency has been to replace this by industrial applications. If the requirements for admission can be extended to include the elements of chemistry and physics, with some botany or zoology, the engineering student will enter with broader views, a keener power of observation, and a scientific spirit, that will greatly increase his chances for success in technical studies.

The general increase in requirements for admission tends to raise the average age of the student. It is now usually the case, owing to the greater length of time needed in preparatory work, that the average age of the classical student is one year higher than that of the engineering student; or the former has had one more year of training than the latter. One more year of training means much as an element for success; one more year in age means an increase in judgment, which is of the highest importance for a proper appreciation of the work of the course. The older men in a class usually do the best if not the most brilliant work, and after graduation their progress is the most satisfactory. It thus appears that all tendencies that raise the age of entrance are most important ones and deserve hearty encouragement.

---

*Presidential address before the Society for the Promotion of Engineering Education at the meeting in Buffalo, N. Y., Aug. 20, 1896.

**Professor of Civil Engineering in Lehigh University.

Having now considered some of the general elements and tendencies in engineering education, it will be well to take up the program of studies, especially in regard to those subjects that are common to all technical courses. The three volumes of the transactions of this Society, contain many carefully prepared papers and interesting discussions which enter into questions of detail concerning nearly all topics in the curriculum. Here, however, can only be noted briefly the main lines of development and the indications for future progress.

Mathematics is undoubtedly the most important subject in all courses of engineering study, and it has been demanded for years that it be taught with great thoroughness. This demand has been met more completely in the independent engineering colleges than in the engineering courses of the universities. Much, however, remains to be done in this direction, and probably it cannot be satisfactorily accomplished until a change in method has been effected. The fundamental element in the charge of method must be, it seems to me, in a partial abolition of the formal logic of the text-books, and an introduction of historical and utilitarian ideas. Mathematics is a tool to be studied for its uses, rather than for its logic or for the discipline that it can give; hence let its applications be indicated frequently and not be systematically kept out of view. If the student gains the impression that his mathematical exercises are merely intended to train the mind, his interest and his progress will usually be slow. If, however, he learns what mathematics has done in the past, how it joins with mechanics to explain the motions of the distant planets, as well as to advance the material prosperity of man, there arises an interest and a zeal that helps him to overcome all difficulties.

The great advantage of numerical exercises in all branches of pure and applied mathematics, and the deplorable lack of good preparation in arithmetic have been expressed by many educators. In numerical computations the average engineering student is weak in spite of the numerous exercises in his practical work. To remedy this defect better instruction in arithmetic is demanded in the common and high schools, while in engineering colleges the teachers of mathematics should constantly introduce numerical work and insist that it be done with a precison corresponding with the accuracy of the data.

Next to importance in mathematics comes mechanics, the science that teaches the laws of force and motion. In most institutions the rational is separated from the applied mechanics and often taught by the mathematical department. Probably less improvement has resulted in the teaching of rational mechanics during the past quarter of a century than in any other subject. That mechanics is an experimental science whose laws are founded on observation and experience is often forgotten, and the formal logic of the text-books tends to give students the impression that it is a subsidiary branch of mathematics. The most interesting history of the development of the science is rarely brought to the attention of classes, and altogether it appears that the present methods and results are capable of great improvement.

It should not be overlooked, however, that in recent years the so-called absolute system of units has been introduced into mechanics, and is now generally taught in connection with physics. Here the pound or the kilogram is the unit of mass, while the unit of force is the poundal or the dyne. Although this system possesses nothing that is truely absolute, it has certain theoretical advantages that have commended its use, notwithstanding that no practical way of measuring poundals has been devised except by the action of the force of gravity on the pound. Engineers have continued to employ the pound weight as the unit of force, and the calculations of the physicist must be translated into the units of the engineer before they can be understood. The student of rational mechanics thus has the difficulty at the very outset of two systems of units, and great care should be taken that each be thoroughly understood and the relations between them be clearly appreciated by application to many numerical problems. In view of these and other difficulties, and of the novelty of the subject in general, it appears that some engineering colleges do not give to rational mechanics as much time as its importance demands.

Physics in some colleges, is taught by a course of five or six exercises per week, extending over a year, while in others the elements are required for admission and the regular course is correspondingly abridged. The marvelous development of electrical theory and practice has naturally tended to make this the most important topic in the course, sometimes indeed to a material abridgment of mechanics, acoustics, thermodynamics and optics. Considering how great is the importance of each branch of physics and the advances that are made every year in new directions, it may also be concluded that more time can be profitably given to both theory and to experimental work. Physics is a fundamental subject whose principles and results are of constant application in every walk of life, and a student who thoroughly covers a well arranged course has gained a mental discipline and a scientific habit of mind that will be of greater value than the technical details of a purely engineering specialty.

Undoubtedly the most powerful tendency in engineering education has been in the direction of the development of those special technic subjects which may be grouped under the name of Construction and Design. In civil engineering this has led to plans for railroad, water supply, and bridge constructions; in mechanical engineering to engine and machine design, in mining engineering to projects for mine plants, and in electrical engineering to the design of dynamos and motors. These courses have been demanded by the public and by the students themselves, and have been often elaborated to an extent beyond the best judgment of teachers of engineering. To the extension of such courses there is no limit, but it is a question whether the process has not already gone too far. For instance, it would not be difficult to arrange a course of twenty or thirty exercises on water pipes in which should be discussed all the methods of manufacture and processes of laying cast-iron, wrought-iron lap-welded, steel-riveted, and wooden mains, together with a comparison of their relative economies under different conditions in different parts of the country. These lectures, however, would plainly be of such a technical nature that the advantage to the student would be slight; they would give valuable information but little training.

In all courses in construction and design the practical limit seems to be reached when the exercises are of such a nature as to give mere information and little scientific training. The aim of all education, and of engineering education in particular, should be to render the student conscious of his mental power and sure of applying it with scientific accuracy so as to secure economy of construction. Fundamental principles are hence more important than the details of a trade, and all exercises in design should be arranged so that the student may think for himself rather than blindly copy the best practice of the best engineers.

The subject of applied mechanics, which occupies an intermediate place between rational mechanics and the work in design, has been so differentiated that the mechanics of materials is now almost the only topic common to all engineering courses. The strongest line of development has here been in the introduction of testing machines and in the making of commercial tests. This work is of high value, although it may be doubted if the use of one or two large testing machines is as advantageous as that of many smaller ones which are designed especially to illustrate principles. The student of the present day enjoys, however, advantages that were unknown a quarter of a century ago, and the marked progress in applied mechanics, from both the scientific and technical point of view, is a source of congratulation.

English and modern languages are generally called culture subjects, and it is well known that of all the topics in the engineering course these are the ones in which students have the least interest. The great importance to an engineer of being able to clearly and correctly write his own language can scarcely be overestimated. Further it may be said that no engineer can hope to attain eminence unless he can read German and French literature. These opinions have long been held, and furthermore it has been recognized that engineering students and graduates are often lacking in that general culture which the world demands as one of the conditions of success. Great improvements have been made in the methods of teaching English and modern languages, and probably still greater ones are yet to result. In the ideal engineering colleges of the future, perhaps these subjects will be required for admission, as is now done by at least one institution, but at present they must generally be taught. The main line of improvement to secure better results will be, it seems to me, in partially abandoning the idea of culture and placing the instruction upon a more utilitarian basis. If English be regarded as a means to an end instead of linguistic drill, if the aim of teaching French and German be to read fluently the language of to-day instead of laboriously to decipher the meaning of the poets of centuries ago, true zeal on the part of students will arise and a truer culture will result.

At the close of the college course the student presents a thesis showing his ability to apply the principles and rules of engineering in the investigation or design of a special problem. The tendency has been strong to abandon subjects which involve mere description or compilation, and to insist upon those that will require the student to exercise his own powers. Thus the value of the work to the student has been greaty increased, and the theses of each class are a source of stimulus to the following ones. Although the view held by some that theses should be monographs setting forth important conclusions of original investigations, is one that can not in general be realized, it is a gratification to note that each year a few theses are produced which are sufficiently valuable to warrant immediate publication.

The formation of engineering clubs among students for the discussion of the details of professional work is one of the most important tendencies of recent years. No exercise is so valuable to a student as one entirely originated and performed by himself, and the preparation of a paper which is to be presented to and criticized by his fellows ranks highest of all among such exercises. Recently there has been forced upon my notice a remarkable activity in the three engineering clubs of a certain engineering college, more than fifty papers having been read and discussed during the year by a total of about three hundred and fifty students, besides a number of others read before the mathematical club. In meetings of this kind the scientific and economic questions under discussion in the engineering journals receive a detailed attention which the professor in the class room often finds it impossible to give, while the advantage to students in expressing themselves in debate is very great.

Occasional lectures to classes by practicing engineers have been introduced in many institutions during the past decade, and with uniformly good results. In engineering education there is no conflict between theory and practice, and every professor cordially welcomes distinguished engineers to explain their great structures and achievements to his classes. It is an inspiration to students to see and hear those men who have so successfully applied sound science to economic construction, and whose influence has been uniformly to elevate the standard of the profession.

After four years of work the engineering student receives his degree and is ready to commence the actual work of life. What the letters are that designate the degree is a matter of small importance. Moreover, if we examine the lists of the alumni who graduated ten or fifteen years ago, the conviction arises that their particular course of engineering study has not been an absolute factor in determining their actual line of engineering work. It is found that graduates in civil engineering are engaged in mining, in machinery and in electricity, and that graduates in other courses are employed upon work in which they received no especial technical instructions. Thus it appears, also, that the particular course of engineering study is not so important a matter as students and the public generally suppose. In fact a young man thoroughly grounded in fundamental principles and well trained how to apply them, has almost an equal chance for success in all branches of engineering practice.

Looking now over the field of tendency thus briefly outlined, it is seen that there has been ever present a powerful impulse towards specialization, to which, indeed, nearly all others have been subordinated. This has demanded a higher standard of admission, great thoroughness in all fundamental subjects, and a rigid adherence to scientific methods. Engineering education has had an active and healthy growth. It now enjoys the respect and confidence of the public, and its future is sure to be more influential than its past. It is not specialization that has caused its success, but rather the methods which specialization has demanded. Those methods have resulted in imparting to students zeal and fidelity, a love of hard work, of veneration for the truths of science, and a consciousness of being able to attack and overcome difficulties; these elements of character are, indeed, the foundation of success in life.

Looking now forward into the future it is seen that in our efforts for the promotion of engineering education a wide field for work still lies open. The student should enter the engineering college with a broader training and a more mature judgment. The present methods of instruction are to be rendered more thorough and more scientific. In particular, the fundamental subjects of mathematics, physics, and mechanics, are to be given a wider scope, while the languages and the humanities are to be so taught as to furnish that broad, general culture needed by every educated man. In general let it be kept in mind that education is more important than engineering, for the number of men who can follow the active practice of the profession will always be limited. Hence let it be the object of engineering education to influence the world in those elements of character that the true engineer possesses, so that every graduate may enter upon the duties of life with a spirit of zeal and integrity, with a firm reliance upon scientific laws and methods, and with a courage to do his work so as best to conduce to the highest welfare of his race and his country.

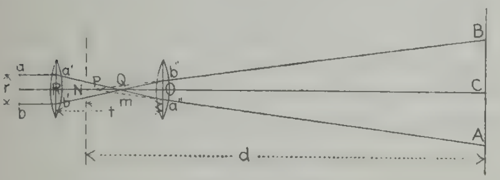
THE RICHER TACHYMETER.

By F. D. Lyphart, C. E.

This instrument has been in extensive use in Europe for a number of years and is called after its manufacturers, Maison Richer, Guyard, Canary & Co., successors, 13 Rue de la Cerisaie, Paris. It chiefly differs from American stadia instruments in being equipped with a so-called "analytic lens." This lens is inserted in the telescope between the object-glass and the wires, and its object is to do away with the customary constant, and to afford a means of perfectly adjusting the instrument for the correct reading of distances, simply by altering the distance of this lens from the object-glass.

The following history and theory of the tachymeter is taken from the work of Dr. Charles M. Schlos on "Surveying and Leveling." The analytic lens was originally introduced by an Italian, Prof. Porro; but it was improved upon and adapted to practical use by a French civil engineer, I. Mainot. In a work published by the latter, and describing the modified tachymeter, he gives careful hints for the employment of the instrument in the field, and for the calculation and plotting of the results of surveys made with it.*

In describing the theory of the tachymeter, for the sake of simplicity, a horizontal line of sight is assumed in the accompanying demonstrations, though the same reasoning will apply to an inclined position of the telescope. In the figure, a′ b′ is the analytic lens; lines are drawn from the stadia wires a and b parallel to the axis of the telescope, and these lines, on passing through the lens meet at the focus Q. When they meet the object-glass they are again broken and strike the rod at A and B; while the projection of the latter lines it would intersect at a point P, back of the focus Q. The distance P C is proportional to the reading A B on the rods; and if the dotted line represented the axis of the instrument, we would have for the required distance d the equation:



$$d = PC + PN = k\,AB + PN.$$

If P N can be made = 0 the apex of the triangle A P B will be moved to the center of the instrument, and the equation will become:

$$d = PC = k\,AB$$

and the constant is eliminated. Since P is the vertical image of the point Q, so far as the object-lens is concerned, we have:

$$\frac{1}{OQ} - \frac{1}{OP} = \frac{1}{F}$$

F being the focal distance of the object lens, and consequently:

$$OP = \frac{F \times OQ}{F - OQ}$$

If f = the focal distance of the analytic lens and F = distance between this lens and the object-glass, we have

$$OP = \frac{F\,(t - f)}{F + f - t};$$

and if m is taken as representing the distance between the object-glass and the center of the instrument:

$$PN = ON - OP = m - \frac{F\,(t - f)}{F + f - t}$$

With P moved to the center of the instrument:

$$PN = 0, \text{ or } m = \frac{F\,(t - f)}{F + f - t};$$

hence

$$f = t - \frac{m \cdot F}{m + F}$$

The above is the formula for the analytic lens. For the coefficient k, which expresses the proportions of the real distance to the reading on the rod, we have

$$k = \frac{CP}{AB} = \frac{OP}{a''\,b''} = \frac{F\,(t - f)}{F + f - t} \cdot \frac{1}{a''\,b''}$$

The triangles Q a″ b″ and Q a′ b′ being similar, we have the equation—

$$\frac{a'\,b'}{a''\,b''} = \frac{QR}{QO};$$

or, if we call the distance of the stadia wires from each other = r, we have

$$\frac{1}{a''\,b''} = \frac{f}{t - f} \cdot \frac{1}{r};$$

consequently,

$$k = \frac{F\,(t - f)}{F + f - t} \cdot \frac{f}{t - f} \cdot \frac{1}{r} = \frac{F\,f}{F + f - t} \cdot \frac{1}{r}$$

or,

$$r = \frac{F\,f}{F + f - t} \cdot \frac{1}{k}$$

This equation gives the distance of the stadia wires from each other for a fixed value of k, generally taken either at 100 or at 200. It is, however, practically impossible to place the stadia wires exactly at the required distance apart; and, as a rule, k is not exactly 100 or 200. The last equation but one shows, however, that k depends on the value of t, the distance between the analytic and the object lens. Consequently, by checking this distance, k can be given the exact desired value, and the instrument can be adjusted for the correct reading of distances.

By changing t, P N will not remain exactly equal to zero; but the resulting inaccuracy is so small that it may be safely neglected in stadia surveying.

In the Richer Tachymeter the analytic lens is made movable; but this arrangement is objectionable, because it is necessary to take the telescope apart to alter the position of the lens, and a perfect adjustment can only be made after several trials. It is suggested that a more convenient means could be devised which would permit a backward and forward movement of the lens, without turning around and without affecting the line of collimation.

Messrs. Buff & Berger, of Boston, refer to the analytic, or Porro lens in their "Handbook and Illustrated Catalogue," and object to it on the ground that it disturbs the line of collimation and unfits the instrument for accurate work. This is true for use where extreme accuracy is required. But the writer has found the Richer Tachymeter of great advantage in ordinary engineering surveys, and in the hands of an expert it gives surprisingly satisfactory results. It is a favorite instrument among European engineers for railway surveys in rolling or mountainous country, as it favors quick work and gives the engineers a reliable means of checking the measurements. Mr. W. F. Shunk is certainly right when he says in his "Field Engineer" that: "Astronomical nicety, whether with transit or level, in an ordinary railroad survey is a mere waste of time."

Porro's lens is objectionable, however, in causing a loss of light, just as in the case of any extra lens; and on this account it should only be used in an inverting telescope. If the figures on the stadia rod are painted upside down, much trouble, on this account, would be avoided. In the Richer Tachymeter the wires are replaced by lines etched on the plane side of the field lens of the eye-glass, which is a Ramsden lens. It is also worth mentioning that the graduation, both on limb and vertical circle is centesimal instead of sexigesimal as usual. This is done with a view of facilitating the reading of the metallic logarithmic slide-rule which takes the place of tables in the use of this instrument. The objection to this graduation is that it makes the instrument unsuitable for running in curves and for similar purposes, especially when American field methods are employed.

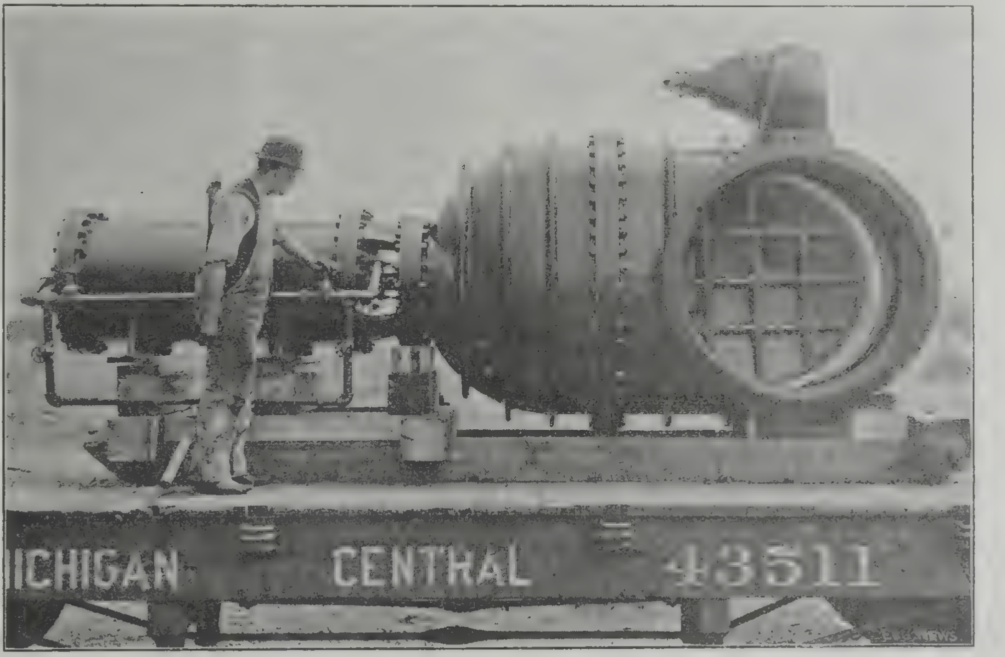
A 42-INCH HYDRAULIC VALVE.

The time and labor required in opening or closing an ordinary geared valve on large water mains is so great that these devices do not receive, in some cities, as many tests to determine whether they are in good working order as the good of the water-works system demands. Aside from this, there are times when it is highly desirable to shut a valve very quickly, and it is always advantageous to operate the valve system or any portion of it with a minimum of time and labor. Obviously one of the simplest means of improving on gear valves operated by hand is to utilize the pressure existing in the water mains to move the valves. This has been done on a line of 42-in. pipe in Detroit, for which the Michigan Brass & Iron Works of that city has furnished twelve 42-in. valves. The same company has also made six 30-in. hydraulic valves for the water-works of Toledo, O.

One of the 42-in. valves loaded on a car for shipment is shown by the accompanying view, from which its general design will be evident. This view does not show the auxiliary hand pump through which the feed to the hydraulic cylinder is made. This pump is for use when there is no pressure on the main, or in case of some emergency. Another feature of the device not shown by the view is designed to prevent the closing the valve under pressure without having the by-pass open. To guard against this, two gages are used, one connected with the by-pass on each side of the gate. By watching the gages the operator can see whether everything is working properly, and if not he can stop the large gate by simply closing the valve on the feed or outlet gate. All the trimmings of the valve are carried on heavy bronze rollers which operate on bronze tracks imbedded in the base of the valve. All contact surfaces bring bronze against bronze. The 42-in. valve complete, without pipe, weighs 14,000 lbs.



VIEW OF 42-IN. GATE WITH HYDRAULIC PISTON ATTACHED, FOR THE WATER-WORKS OF DETROIT, MICH.
Made by the Michigan Brass & Iron Works.

The pressure at Detroit is nominally 35 lbs. per sq. in. in the line on which these valves are placed. The valves there, the manufacturers state, have been closed in one minute. The time of operation, however, is under absolute control so that the valve can be moved as slowly as may be desired. For the above information we are indebted to Mr. Fred. H. Cozzens, Secretary and Treasurer of the Michigan Brass & Iron Works.

Shortly after the valves were placed at Detroit, Mr. L. M. Case, Superintendent and Secretary of the water-works, wrote us in response to our inquiry that they were giving satisfaction.

ENGINEERING NEWS
AND
AMERICAN RAILWAY JOURNAL.

Published every Thursday at Tribune Building, New York.
Entered at the Post Office, New York, as Second Class Matter.

LONDON AGENCIES: KEGAN PAUL, TRENCH, TRUEBNER & Co. (Limited), Paternoster House, Charing Cross Road; SAMPSON LOW, MARSTON & Co., (Limited), St. Dunstan's House, Fetter Lane.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32d *week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

In connection with the editorial in our last issue on the subject of the export of American manufactures, it is of interest to note that the Carnegie Steel Co. has just secured an order for 9,000 tons of steel rails for Japan. Concerning this the New York "Journal of Commerce" says:

> The order is for 9,000 tons for delivery up to the end of the year, and was placed with the Carnegie Steel Co. by Mitsui & Co., of Japan, after inviting bids in England and in this country. While the price paid could not be learned it may be said that the bid of the Carnegie Co. was sufficiently below the English market to justify its acceptance in spite of the higher freight rates from this country. The contract calls for 60-lb. rails. * * * *
>
> This is the second large order that has been placed in this country for steel rails on Japanese account, the Illinois Steel Co. having filled an order for 10,000 tons a few months ago, and it is expected that the steel-rail business with Japan will develop into a steady and important item of trade. It is expected that the demand in Japan for railway material will in the near future show a marked increase.

It would appear from the above item that American manufacturers can beat those of Europe in steel rails as well as in cotton cloth, even when seriously handicapped in the competition.

◆

The paper on the pooling of freight equipment which we print on another page discusses a subject of the greatest importance to the railways of the country. There is probably not a single reform which the railway companies of the country could institute (unless it be a radical revolution in the rate-fixing and traffic soliciting departments), which would bring such great returns as a general agreement to pool freight car equipment.

We have often pointed out that the expenses of handling freight in terminals and yards are becoming a larger and larger proportion of the total freight traffic expenses. The latest statistics show that there are over one-fourth as many locomotives engaged in switching service as in road service on freight trains in the whole United States and in some sections the proportion rises to one-third. This does not tell the whole story either, for the locomotives of way freight trains spend a large part of their time in switching work at unimportant stations. An enormous proportion of this switching service would be needless if the railways would only agree upon some plan of joint ownership. And this is only one, and by no means the most important of the benefits that would result from such a system.

The fact is that the railways have progressed so far toward common use and ownership of their freight equipment, that actual joint ownership is merely an obvious next step in advance. At present the car which one railway company owns spends half or more of its time in the service of other companies, and is treated in many respects when it is away from home exactly as if it were common property. Under the proposed pooling arrangement a company owning cars would receive, it would appear, just as much revenue from them as at present, would be more sure than now of having cars to furnish its shippers in times of heavy traffic, and would share with all other railways the benefits resulting from the pooling which Mr. Cavanagh's paper well sets forth.

The fact that so many cars are owned by equipment trusts might be thought a difficulty; but this could easily be overcome by leasing the cars to the proposed joint equipment association instead of transferring them outright. It is to be hoped that the railway presidents, who have of late shown so commendable a disposition to work in harmony with each other, may see their way clear to arrange for co-operation in this important field.

◆

The metric system and the advisability of its compulsory adoption in this country was before the Engineers' Club of Philadelphia for discussion last spring, and the July number of the club's "Proceedings," which has just come to hand, contains a report of the discussion and the action taken, which is of no small interest. The discussion was started by the receipt by the club of a circular letter from the American Metrological Society, asking the club's signature to a petition favoring the passage of the metric bill now before Congress, and the reading of the letter "evoked a very spirited discussion," in the words of the official minutes. Finally a committee of five was appointed to report at a later meeting what action the club should take in the matter. At the meeting on April 18 this committee presented a report favoring the approval by the club of the metric bill, and further extended discussion and reading of correspondence took place. It was finally decided to submit the question of the adoption of the committee's report to a letter ballot; and at the next meeting of the club the result of the ballot was announced, 100 favoring the report and 60 being against it.

From a condensed report of the discussion which appears in the "Proceedings," we find that Messrs. Wm. and Coleman Sellers, Wilfred Lewis and S. M. Vauclain were the chief opponents of the metric system. Those favoring it, on the other hand, included Mr. Geo. B. Roberts, President of the Pennsylvania R. R.; Mr. Francis Schumann, President of the Tacony Iron & Metal Co., which uses the metric system in its shops; Mr. A. Falkenau, who also has used the metric system, and many others.

◆

A loop terminal has very generally been acknowledged to have many important advantages over a head-house or dead-end terminal, more especially for lines having a heavy traffic of one class of trains, as on city and suburban lines. These advantages are especially important in the case of elevated railways, where the great majority of the traffic is simply an in and out movement for each train, with only the switching necessary for changing engines and changing the train from the up-town to the down-town track, or vice versa. The amount of room required for the loop system, however, has generally prevented its adoption on elevated railways. In another column we describe a loop line which will be a terminal for the joint use of four elevated railways. On this line there will be a daily traffic of 1,000 to 1,500 trains, and it is a notable feature that no reverse movements will be required, the incoming trains of each line passing round the loop to the outgoing track. This is a city terminal, and there will be no changing of engines or putting on of new cars, all such work being done at points on each individual line. Apart from the great convenience which will be attained in the prompt handling of the traffic there will be a great convenience for through passengers from one part of the city to another, as they can leave an inbound train from the north or west side at a station on the loop and take an outbound train for the south side at the same station. It will be evident that to effect the necessary connections between the several lines there must be a somewhat intricate system of switches, and that to safely and promptly handle the traffic a very complete system of signaling and interlocking will be required, and these points appear to have been fully covered in the loop line above mentioned, the main principle on which the plans have been prepared being that of ensuring the greatest safety and efficiency, while the cost of the work has been but a secondary consideration. This is undoubtedly the right way to go to work, more especially in a case where there will be such a heavy traffic at the outset, and where (judging from the experience of other elevated railways) the traffic is so likely to rapidly increase. The advantages of the loop system were pointed out by Mr. W. L. Derr in a paper on "Railway Yards and Terminals," in our issue of June 9, 1896, and the system has been somewhat extensively adopted for street railways, but it has been very little applied to steam railways. In fact at present we can only mention the Chicago loop line, the loop terminal of the Brooklyn Elevated Ry. at the Brooklyn Bridge, and the terminal of the Mexican National Ry. at Manzanillo (Eng. News, July 5, 1894). An objection frequently made is the amount of space required, but this objection has been very much exaggerated, and we question whether there are many places where the system could not be applied if desired.

◆

In the Province of Manitoba, civil engineering is now a "close profession," the government of that province having passed a law at its last session, putting certain restrictions upon the practice of engineering, in accordance with the request of a committee appointed by the Canadian Society of Civil Engineers. The work which has been done by that society toward the establishment of the engineering profession upon a similar basis to that of the other professions was summarized in our issue of April 30, 1896, and we reprint in another column the law recently passed by the Manitoba legislature. It will be noted that its provisions are exceedingly mild. It is declared in substance that after July 1, 1896, no person shall be entitled to call himself a civil engineer or to act as an engineer in connection with any public work involving over $500 expenditure, unless he is a member of the Canadian Society of Civil Engineers or of some other national society of civil engineers "of good standing," or unless he was practising as a civil engineer in Manitoba at the date of the passage of the act, or unless he is a "duly qualified civil engineer" and entitled to use the title of Civil Engineer by virtue of some statute in force in the province, or unless he holds the degree of Civil Engineer conferred by some institution of learning in the province. The breadth of these exceptions is praiseworthy; but it is also to be noted that the law provides no pains or penalties for those who disregard its provisions. It states who shall be entitled to use the title "Civil Engineer," and to practise the profession, but if any one chooses to write C. E. after his name, or to practise as a civil engineer, without the qualifications laid down, the law neither defines the nature of his offence nor specifies its punishment.

◆

The presidential address of Prof. Mansfield Merriman before the Society for the Promotion of Engineering Education is an admirable summary of the present tendencies in engineering education in this country and it can be read and studied with profit by practising engineers as well as by the professors in engineering schools. Every engineer, so long as he continues in active practice, must be to a greater or less extent engaged in the work of engineering education—training one pupil, himself; and so long as he gains in ability, it is because, consciously or unconsciously, he is carrying on the work of self-education. We might comment upon the various topics which are brought forward by Mr. Merriman, but he has so tersely and ably set forth principles and ideas with which this journal is in hearty accord that we can do no better than cordially commend his address, as admirably setting forth the directions in which progress should be made. We desire, however, to call especial attention to his remarks respecting the tendency toward over-specialization in the engineering schools. He well says that the particular course of engineering study to be pursued by a student is by no means so important a matter as students and the public generally suppose. The young man thoroughly grounded in fundamental principles and well trained in the methods of applying them has almost equal chances of success in all branches of engineering practice.

◆

In our issue of July 30 was published a report of the U. S. Geological Survey on the "Mineral Products of the United States" for the calendar years 1886 to 1895. Mr. David T. Day, Chief of Bureau, now sends us a new chart which, from revised figures of the Director of the Mint, corrects the productions of gold and silver, in 1895, as published in the former chart. To make the corrections plain we publish both the original and corrected figures for 1895, as follows:

	Original.		Corrected.	
Coin'g val.:	Quantity, Troy oz.	Value.	Quantity, Troy oz.	Value.
Silver....	47,000,000	$60,764,300	55,727,000	$72,051,000
Gold......	2,272,629	47,000,000	2,254,760	46,610,000

◆

WHO SHOULD PREPARE SPECIFICATIONS?

In a letter which we recently received from a well-known engineer the following sentence occurred:

> The preparation of specifications has always been regarded as the function of engineers, who ought to know the character of the work they want, and it is not desirable that this time-honored custom should be changed.

We presume that there are not a few engineers who hold similar views and who regard the formulation of specifications by manufacturers in this or that or the other field of engineering, as in some sense an infringement on the province of the engineer, and a thing to be resented and condemned. It seems worth while, therefore, to discuss the pros and cons of the question, and see just what the attitude of the profession should be on this important matter.

In the first place let us remember not to use the word engineer in too narrow a sense. The manufacturers of to-day are in very many cases able engineers, just as well educated, just as broadly experienced and often more expert in the special line in which they are engaged than is the average engineer who acts as an adviser to those who purchase their products. Take for example the matter of bridges. No one doubts that the chief engineers of the leading bridge companies are among the most able of living experts in this field of engineering. But the average practising engineer does a little in this line and a little in that, and occasionally is placed in charge of a bridge letting. Is it reasonable to expect that he will be so well posted and so expert in the latest and best practice in bridge work that he can draw as good a detailed specification as can be made by the engineer of a bridge company, who is devoting all his time to this one specialty six days out of seven?

Clearly we cannot decree that the manufacturers or the manufacturer's engineer shall not prepare specifications on the ground of ignorance or incompetence. But it may be urged that the manufacturer should not prepare specifications because he will frame them to suit his interests instead of those of the purchaser. The maker of steel, for example, it may be said, will set his limits of sulphur or phosphorus at a point which will suit the ores that he can purchase most advantageously; the paint manufacturer will specify a paint which will carry a goodly amount of cheap adulterants, without transgressing the requirements; the bridge-builder will draw a specification under which poor riveting may be passed, and light sections will be permissible.

Now it would be idle to deny that there is a tendency for the manufacturers to do things of this sort. They must meet keen competition in the markets, and in order to make their prices compare favorably with those of their competitors they must not agree to furnish too good an article. But on the other hand, there are other powerful forces at work to restrain the manufacturer from writing a specification for an article which shall be distinctly inferior with respect to safety, durability, or appearance. If the steel-maker furnishes metal too high in phosphorus, a serious accident may result and the cause may be traced back to his steel. If the paint-maker substitutes cheaper oils for linseed, his customers will complain of his paint as lacking in durability. If the bridge-builder draws a specification by which defective workmanship is made permissible, one of his bridges may fall and the damage to his reputation may injure his business a thousand times as much as the profit that he might make from drawing too liberal a specification.

Clearly, then, the motives which impel the reputable manufacturer to furnish first-class goods to his customers are very strong; and were specifications drawn by this class of manufacturers alone, probably less fault would be found with manufacturers' specifications; but it must be admitted that manufacturers are not all of this class. There are manufacturers who care nothing for the reputation of their goods—who are not working to build up a business but to reap quick profits. There are others whose policy it is to obtain business not by the merit of their products nor their low prices, but by their ability in securing orders from the officers of corporations who are more concerned to line their own pockets than to protect the interests entrusted to them. Clearly, from manufacturers of these latter classes, we can expect nothing excellent, either in products or in specifications describing what the product should be.

Manufacturers, of honesty and reputation, welcome, we believe, invariably, the preparation of specifications by an able and conscientious engineer, because it protects them from the unfair and unequal competition with manufacturers of the classes we have just described. The energetic and honest manufacturer prefers to bid under a strict specification, which defines in every detail what will be required. He can safely make a close bid on work of that sort. But he detests a competition in which a specification of vague platitudes leaves every opportunity open to dishonest competitors to do business according to their methods. Competition of that sort is not competition at all; it is merely a match at wire-pulling.

Now, it is an unfortunate fact that the engineers in charge of works are too often unequal to the task of writing a strict and detailed specification. How often do we see especial emphasis laid in some one feature in a specification, while others of equal or greater importance are left unmentioned. It is also an unfortunate fact that in too many cases important purchases are made of engineering materials without the advice or aid of any engineer. It is surely better where such purchases are made in open competition to have manufacturers' specifications than none at all.

We believe that the most perfect system of preparing specifications and purchasing goods in existence is that which has long been in use by the Motive Power Department of the Pennsylvania Railroad. It has been described before, but we may briefly summarize its chief features. In the first place all the supplies which the great corporation requires, from steel to soap, are bought under strict and detailed specifications. The original draft of these specifications is made by the company's chief technical experts, and copies of this draft are sent to all the manufacturers in that particular line with which the company has any dealings, with a request for criticisms and suggestions. These are all given careful consideration and such are adopted as seem to promise any real improvement. Upon these finally amended specifications all goods are bought. But the process does not stop here, for all specifications are held open to amendment, and are revised from time to time in accordance with increased knowledge or improved processes.

We can imagine no system that could be fairer to all parties concerned, or better calculated to secure for the purchaser an excellent quality of goods at the minimum price consistent with good quality. It may be said that this system is only adapted to the purchase of regular lines of supplies by a great railway corporation; but we believe that many much smaller corporations and many municipal corporations could adopt such a system with profit. There is no reason why a city should not have its standard specifications for bridges, cement, sewer work, paving of various classes, etc., and many cities, indeed, already have them. But the main point on which we desire to lay emphasis is the systematic consideration of the opinions of those who are to work under the specifications—both in their original formulation and in their periodic revision.

Of course, it is true that with all possible use of standard specifications by municipal and private corporations, there still will remain a vast amount of contract work for which special specifications must be drawn if the work is to be properly carried out. We do not urge, by any means, that such specifications had better be made by manufacturers or by contractors; nor do we believe that specifications from this source are likely to be adopted by purchasers to economize in engineering expenses. But we do urge that no prejudice should stand in the way of the acceptance of the points of excellence which may be found in specifications prepared by manufacturers.

It is too little understood by the public generally and too little appreciated even by engineers themselves that the plans and specifications for a structure should actually contain the finished work. and do contain it if they are properly drawn. The actual work should be the mere carrying out of what the engineer has built on paper. Bearing this in mind, the importance of excellent and detailed specifications is easily understood. The real engineer seeks aid in the preparation of his specifications from every possible source. He consults the precedents which the experience of the profession has established, and he will not fail to consider and profit by the experience of those whose province it is to carry out in practice the ideas which he originates.

LETTERS TO THE EDITOR.

A Blast Which Wouldn't Go.

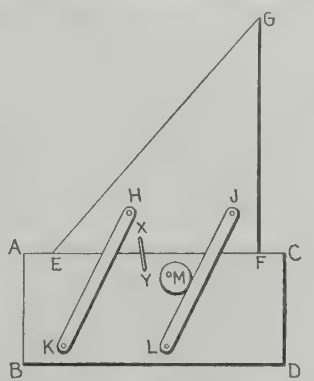
Sir: In blasting coraline rock I placed a charge of 4 lbs. Hercules No. 2 dynamite in a 7-ft. hole, and set it off with single-ply fuse. The cartridge attached to the fuse fired clean without setting off the charge, I then opened the hole to the charge and placed directly over the charge 2 lbs. more of dynamite which also fired clean without setting the charge off. Will some of your readers explain the cause? Truly,

Miami, Fla., Aug. 9, 1896. Wm. Varnedoe.

◆

A Home-Made Section Liner.

Sir: You will find herewith a drawing of a section liner, which may be easily and cheaply made by any one who is the least "handy." A B C D is the base to which the triangle, E F G, is fastened by the brass connecting pieces, H K and J S. The regulator, M, is a circular piece of brass eccentrically fastened to the base and against which the connecting piece, J L, works. X Y is a rubber band to aid in the adjustment, which is easily made by the brass regulator for any width of space from zero to the difference between the two parts of the diameter of the regulator. Very truly yours,



A Home-Made Section Liner.

W. D. Sell, Jun. Am. Soc. C. E.

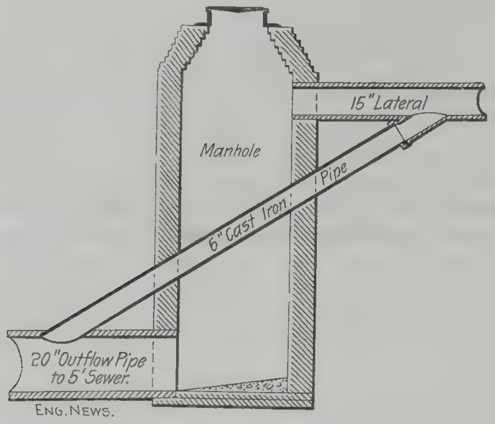
Logan, W. Va., Aug. 1, 1896.

◆

A Problem in Connecting Lateral and Main Sewers.

Sir: In some sewer construction upon which the writer has been engaged recently, a problem arose concerning the solution of which the opinion of other engineers is desired. A 5-ft. brick sewer was being constructed along a main street to replace a sewer which had been constructed at from 4 ft. to 6 ft. higher level. The laterals from the cross streets had emptied into this old sewer at grade; but when the new sewer was built several feet below the old one, the outlets of these laterals were, of course, several feet above its grade. The problem was the best method of connecting these laterals with the new sewer. One of the methods suggested is shown by the accompanying cut. The inclined pipe is a dry weather pipe and is of iron. Very truly, B. H. S.

Chicago, Ill., July 17, 1896.



Proposed Method of Connecting Laterals and Main Sewers, When the Two are at Different Elevations

A Question of Professional Ethics.

Sir: On p. 73 of your issue of July 30, 1896, "E. K." would like an opinion on the question of Engineering Ethics. I think he can find his answer in the 2d, 3d and 4th lines of the second column of p. 75.

Respectfully yours, James H. Harlow.

Pittsburg, Pa., Aug. 14, 1896.

(The point raised by "E. K." related to the propriety of the acceptance by an engineer for a department of public parks of the position of chief engineer of a railway to run through the parks. Mr. Harlow refers, in reply, to the following sentence from an address on "The Legal Duties of Engineers and Architects," delivered before the Engineering Association of the South by Hon. Jas. C. Bradford, of Nashville, Tenn.:—Ed.)

> One of the commonest rules of the law of principal and agent is, that a man shall not serve two masters.

Fire Tests of Loaded Columns.

Sir: Referring to your editorial in your issue of Aug. 13, on the report of work done by the Committee on Fireproofing Tests, permit me to call your attention to a slight error. The hydraulic apparatus has a capacity considerably in excess of the loads put upon the columns during the tests reported. It is so arranged as to allow the use of a hydraulic pressure of 2,500 lbs. per sq. in., while the greatest testing load was only 1,500 lbs. The loads that were actually put upon the columns represented the maximum limits permitted by the building laws of large and prominent cities.

I also note your suggestions in regard to future work and can state that it is the committee's intention to continue these tests so as to cover the various conditions of practice. Just at present, however, the committee is hampered for want of funds. These tests are very expensive to carry out, on account of their being made on full sized members. The funds so far raised have been entirely through voluntary contributions and the committee proposes at an early date to call a meeting of the Advisory Board, in order to take necessary steps for the further continuation of its work. Yours very truly,

H. de B. Parsons.

(We may add with respect to the matter of funds for further tests, that the bulk of the funds thus far expended by the committee were necessarily devoted to the construction of the gas producer, the testing chamber, etc. The actual expense of making the tests, when the plant was once ready, was comparatively small. It is to be hoped, therefore, that ample funds may be forthcoming to continue these tests on an extensive scale.—Ed.)

The Metric System or Duodecimal Notation?

Sir: Will you allow me to say a few words more upon the question of weights and measures, in reply to your editorial of July 30, which has just reached my eye.

You are right in anticipating considerable delay in making any change in our present system. But it is only a question of time, and therefore not worthy of argument. Some change is inevitable. All are agreed on that; so that, too, is unworthy of argument. Any change which is to be satisfactory must be sweeping, and therefore costly and troublesome beyond estimate. This, also, we may as well accept as inevitable, without wasting time in its discussion.

The only question worthy of the time of clear-sighted men is that of what system is to take the place of the present lack of one. Which one will be the most satisfactory and will cost the least to acquire?

In its discussion, do you not find more satisfactory the frank perspicacity of Mr. Herbert Spencer, in his letter to the "Popular Science Monthly" for July, than the cautious circumlocutions of London "Engineering," that most conservative of all the journals which ever stumbled along twenty years behind the leaders of progressive thought? If the prejudices of the ignorant masses are likely to delay this reform, for which we are so athirst, why add to them the prejudices of the enlightened? It is as futile to discuss the probability of the coming of this inevitable step in progress as to hope to evade the law of gravitation. How may it come most easily is the only topic worthy of paper and printer's ink.

Yours truly, Sidney A. Reeve.

(We are by no means certain that a change is inevitable. It is not likely to be made until there is a popular demand for it, and a change in our system of weights and measures, or in our system of notation, would be certain to encounter popular ridicule and opposition, instead of popular approval.—Ed.)

Notes and Queries.

W. P., Little Rock, Ark., asks for information concerning dump scows for use in dredging material where the depth of water to be secured is only 2 to 3 ft.

A MELAN ARCH WITH ROCK FACING AT ATLANTIC HIGHLANDS, N. J.

We illustrate herewith a handsome masonry arch which has just been erected at Atlantic Highlands, N. J., under direction of the Melan Arch Construction Co., of New York city. The arch is of the well-known Melan construction (steel beams embedded in concrete) and has a facing of field stone which gives it an exceedingly picturesque appearance. The arch has a 50-ft. span and has a width of 25 ft. over all, with a 20-ft. roadway. For the Melan construction 6-in. steel beams weighing 13 lbs. per ft. were used, spaced 3 ft. c. to c. Earth filling was placed over the haunches. The road which crosses the arch has a grade of 6% and the arch is built on a skew of 53° 8′.

MELAN ARCH WITH FIELD STONE FACING AT ATLANTIC HIGHLANDS, N. J.
The Melan Arch Construction Co., New York City, Engineers.

Atlantic Highlands is a well-known summer resort on the south shore of New York Bay. The borough government contributed $800 toward the cost of the structure and the remainder of the cost was made up by voluntary contributions by public-spirited citizens. Our photograph shows the surroundings of the arch still in an incomplete condition. These will soon be neatly graded and turfed, and ivy will be planted and trained over the arch. The structure is an excellent illustration of the growing tendency toward the choice of designs of aesthetic merit for bridges located in suburban towns and fashionable summer resorts.

THE POOLING OF FREIGHT EQUIPMENT.[*]

By J. R. Cavanagh.[**]

There is probably not a road in our association but what at some time during the past few years has seen a period when it has simply been impossible to obtain cars to handle the business offering. These conditions were not caused by lack of equipment in the country, but by the existing methods of handling cars. There are to-day at least 25% more freight cars than are necessary to move the largest volume of traffic we have ever been called on to care for. At no time do we find every section of our vast country in want of some class of cars simultaneously; but under the present system there is no provision for moving the surplus equipment from one section to another.

There are in the United States, Canada and Mexico over 1,175,000 freight cars owned by railway companies, representing an investment of about $580,000,000, which has not for years earned enough to pay the interest on the investment, depreciation and repairs.

The question arises—"What can we do to increase the performance of our cars?"

Plan after plan has been suggested; roads have kept on building cars, but with no apparent relief. The only remedy is the general pooling of all freight cars, the adoption of the per diem system, a uniform standard in sizes of cars, and the full enforcement of car service.

Referring to the proceedings of the Eastern railway car service officers in September, 1894, we find the following resolution:

> Resolved, That a general distributing office or clearing house, with subsidiary bureaus, be established for the purpose of regulating and increasing the supply of cars between railways to meet the legitimate demands of traffic.

I believe that the time is not far distant when we have got to come to a general distributing office, or something of the kind. A few contend that it is "too large a subject," "too many conflicting interests to harmonize," etc. The same remarks were made by many of our most prominent railway men when the Joint Traffic Association was suggested, but it came, is here, and apparently to stay.

There has been too much selfishness in the past which has resulted in disaster to the majority. We must unite now on some plan that will stop the enormous leaks caused by:

1. Idle equipment in one part of the country while another part is suffering for want of the same identical cars.
2. The handling of empty cars of similar class in contrary directions on account of route or initials.
3. The switching of empties out of sidings, freight houses, etc., only to switch in the same class of cars to load via lines other than those owning the cars switched out.
4. **Unnecessary switching to get some particular car out** of a string of empties, when the first car is exactly the same kind of a car but with other initials.

---

[*] A paper read before the Association of Railway Officials at Toledo, O., July 21, 1896.

[**] Superintendent of Car Service; C., C., C. & St. L. Ry., Indianapolis, Ind.

5. The expense of traveling car agents, car tracing clerks and car service associations. (The latter will be merged into district bureaus.)

As an illustration, take the sleeping car companies. Were all contracts to be annulled to-morrow between them and the railway companies, twice the number of sleeping cars now in service would not care for the current business, making no provision for equipment needed during large conventions, gatherings, etc.

Take the private stock car companies. No railway company can show up any such average mileage per car per day. While railway companies average 35 to 50 miles, the private car companies run 75 to 100. You see a string of their cars in Montana to-day, at the seaboard in a few days, and a week later away down in Texas or Mexico. Their cars are always in active service because handled by one central authority to meet the requirements of the various sections.

In forming a car pool or equipment company I would recommend that we start in with the box cars first, because that class of cars is in more general demand and in 90% of the cases represents the item of equipment from which we receive most complaints of shortage.

With a view of economy in painting, clerical work, car recording, accounting, etc., I would recommend something after the following plan:

1. Have a distinctive mark to represent the class of car, thus:

"A," for box cars; "B," stable stock cars; "C," common stock cars, single deck, etc.

Abolish all car initials and use the distinctive letters instead.

Each kind would commence at 1 and number up, thus: A box car 34 ft. long (inside) 60,000 lbs. capacity, would simply be marked "A D E," 5,910. In a short time every switchman, bill clerk, auditor's clerk, car distributor, record clerk and employe or shipper would know at a glance what a car was. There would be no necessity of consulting a guide. Instead of reporting a dozen or more initials on car reports, we would simply use the "pool" marks. In many cases this would reduce the number of initials to report over 70%.

Of box cars alone the Guide shows that there are over 630,000, at an approximate valuation of over $310,000,000, and distributed as to lengths as follows:

20 ft. long	275	36 ft. long	15,057
22 " "	33	37 " "	2,393
23 " "	84	38 " "	1,339
24 " "	995	39 " "	957
25 " "	478	40 " "	5,157
26 " "	514	41 " "	150
27 " "	36,615	42 " "	158
28 " "	97,668	44 " "	15
29 " "	39,658	45 " "	31
30 " "	54,743	46 " "	55
31 " "	1,338	47 " "	2
32 " "	30,242	49 " "	2
33 " "	134,311	52 " "	14
34 " "	200,533		
35 " "	7,079		630,176

The first step necessary to form a pool (after the roads have agreed to it) is the establishment of a general or central office in charge of a general manager. Then divide the country into districts, similar to or in conformity with the freight traffic associations, such as eastern, central, etc., each district to be in charge of a district manager or distributor; each road to handle its own distribution as at present; daily reports to be rendered to the district office, which, in turn, consolidates and transmits the same to the central office.

The pool would have to be organized by each road taking as much stock in the equipment company as the valuation of its equipment amounted to, each company to receive its pro-rata earnings as each class of cars it owns in the pool bears to the total number of cars or valuation of that class: Thus all 34 ft. box cars, 50,000 capacity would be marked "A D D." If the L. S. & M. S. Ry. owns 11% of the valuation of all cars in that class, it would receive 11% of the earnings.

If such a thing is necessary the identity of the cars can be preserved by assigning each road's cars of the same class into consecutive series or numbers: Thus, C., C., C. & St. L. Ry., 34 ft., 30 ton box cars 18,000 to 18,999 would be assigned "A D E" 1 to "A D E" 1,000; N. Y. C. & H. R., 52,000 to 55,999 would be assigned "A D E" 1,001 to "A D E" 5,000, etc.

Each road in the pool will be entitled to the same number of cars in each class as it owns in the pool, providing it needs them, and must accept up to its quota when offered for storage.

Compensation should be based on both the earning capacity of car and per diem, if possible. Thus:

30 ton and over, per diem 30 cts., or ⅝ ct. per mile.
25 ton and over, per diem 25 cts., or ½ ct. per mile.
20 ton and over, per diem 20 cts. or ⅜ ct. per mile.
15 ton and over, per diem 15 cts. or ¼ ct. per mile.
Under 15 tons, per diem 10 cts., or ⅛ ct. per mile.
For all cars in excess of 39 ft. add an agreed per cent.

By graduated compensation as suggested above, in addition to the justness of the proposition, roads would use only such cars as are necessary to handle the business. Thus, a road that could use ¼ ct. cars would not call for ⅝ ct. cars, allowing the latter to go into such service as the ¼ ct. equipment would be incapable of handling.

Car repairs could be based on proportion of mileage or per diem, or on such basis as may be agreed upon by the Master Car Builders of lines interested. This means uniform standards sooner than under present methods.

The car pool means decreased expenses from

1. The increased performance of all cars, permitting the handling of a given quantity of business with a minimum number of cars—obviating the building of any new equipment for five or six years.
2. Decrease in empty and foreign mileage.
3. Saving in switching at terminals and stations.
4. Reduction in train mileage.
5. Decrease in inspectors, repair shops, material, maintenance of way, car repairs, wheelage or trackage over foreign rails, clerical work, telegraphing, etc.
6. Increased earnings from greater supply of cars and reduction in expenses.

The district manager for the Joint Equipment Association would have charge of distribution of equipment, handling of demurrage or car service matters, car repairs and all matters pertaining to the equipment. This would be an improvement over present methods, for the reason that the car owner would have a representative at every point seeing that the best service was gotten out of the equipment, while under present conditions at many points foreign equipment is abused, misused and held on account of being a "wanderer from home."

After the box cars have got to working in the pool, then add stock or other classes as fast as considered advisable or as the trustees representing the owners may decide.

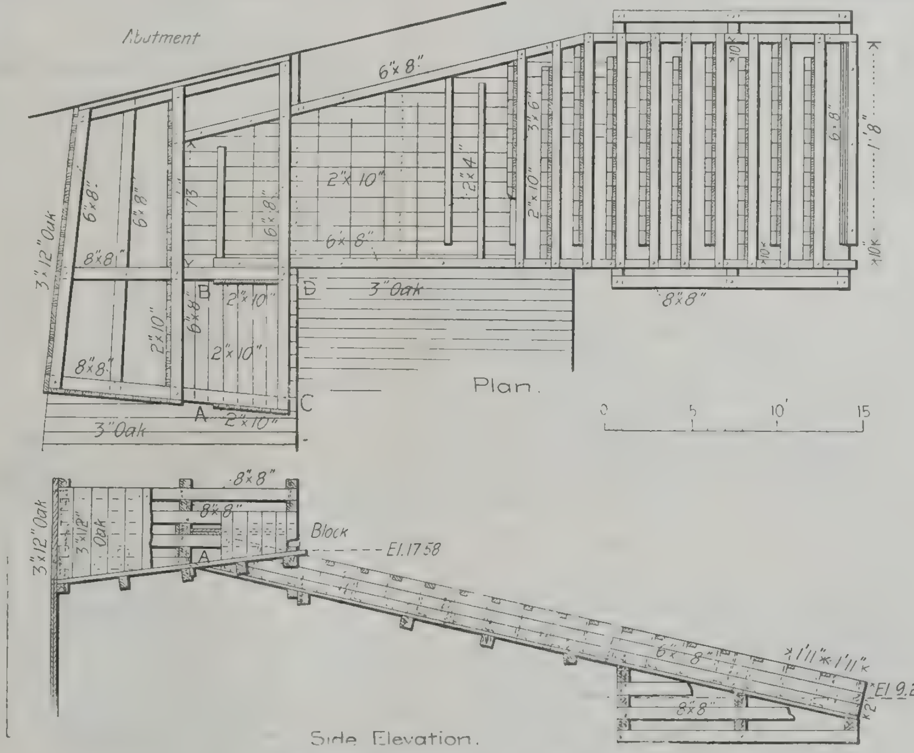
The difficulties to be overcome are not as great as might appear upon first consideration of the subject, as an organization can be formed by which all roads desiring to become members (stockholders) would be protected equitably in their rights.

Last fall I took the trouble to inquire about the probable loss to railways from cars lying idle at junction points, switching, etc. Replies were received from a number of representative men. The lowest estimate showed from loss of revenue, cost of transfer, and loss in car mileage for one year over $25,000,000, and the above simply on account of owners not allowing their cars to go beyond junction point.

◆

FISHWAY FOR DAM AT STERLING, ILL.

We illustrate herewith a fishway built in the dam of the Sterling Hydraulic Co., at Sterling, Ill., under the direction of Mr. L. L. Wheeler, M. Am. Soc. C. E., to whom we are indebted for the blue print from which our illustration has been prepared.



FISHWAY IN DAM AT STERLING, ILL.
Designed by L. L. Wheeler, C. E.

Mr. Wheeler states that the plans furnished in response to his application to the U. S. Fish Commission and the Illinois Fish Commission did not appear to be adapted to the conditions he had to meet or likely to be satisfactory if followed. The form and dimensions of the cribs and fishway were in part fixed by local conditions, and they were built from remnants left from repairing the dam. The cribs were packed with stone, except over the upper end of the fishway. The timbers A C and B D are simply blocked on the crest of the dam, leaving the water free to spill over the crest C D. The openings A B are of equal size, and it is intended that the head on the opening B shall be practically constant. The minimum distance the water travels in overcoming a fall of 8.4 ft. is 200 ft.

◆

CIVIL ENGINEERING A CLOSE PROFESSION IN MANITOBA.

It is probably not known to many of our readers that civil engineering is now a close profession in the province of Manitoba, Canada, and that the indiscriminate use of the title of "civil engineer" or "C. E." is illegal, as is also the practice of engineering by any but a member of a national association of engineers.

We have from time to time recorded the steps taken and the progress made by the Canadian Society of Civil Engineers in its movement to secure legislation making the society a close corporation, and the matter was editorially discussed in our issue of April 30, 1896. At the last annual meeting it was voted that the council should appoint a committee of three in each province to see if the government of the province would pass the proposed bill to limit the practice of civil engineering to members of the Canadian Society of Civil Engineers. In Manitoba the matter was acted on very promptly, and the bill was at once submitted to and passed by the government of that province, which has thus the distinction of being the first government in the world to make engineering a close profession. It may be noted that in all the Canadian provinces the practice of surveying has been limited by law to surveyors who have passed the government examination, while in some (including Manitoba) only members of the provincial society of surveyors are authorized to make surveys.

We are indebted to Mr. H. N. Ruttan, M. Am. Soc. C. E., City Engineer of Winnipeg, Man., for a copy of this law, and we reprint it herewith in full. The principal feature of the bill is contained in the last paragraph, and we have briefly commented upon it in another column.

An Act respecting the Profession of Civil Engineers.

(Assented to 19th March, 1896.)

Whereas, it is deemed expedient for the better protection of the public interests and for the general advancement of Mechanical Science, and more particularly for promoting the acquisition of that species of knowledge which has special reference to the profession of a Civil Engineer, and to encourage investigation in connection with all branches of knowledge connected with the profession, and in order to enable persons requiring professional aid in any work, to which such knowledge of Civil Engineering is applicable or necessary, to distinguish between qualified and unqualified Civil Engineers;

Therefore,

Her Majesty, by and with the advice and consent of the Legislative Assembly of the Province of Manitoba, enacts as follows:

1. This Act may be cited as "The Manitoba Civil Engineers Act."

2. The Civil Engineers of Canada, heretofore incorporated by an Act of the Parliament of Canada, being Chapter 124 of the Acts passed at the Session held in the 50th and 51st years of Her Majesty's reign, under the name and style of "The Canadian Society of Civil Engineers," shall be a body corporate by the name aforesaid, having perpetual succession and a common seal, with power to acquire, hold and dispose of real and personal property for the purposes of its constitution, and to sue and to be sued in the manner usual with such corporations.

3. All persons who, on the day this Act comes into force, are members of the said existing Canadian Society of Civil Engineers, and all persons who shall hereafter be admitted as members of the Society hereby incorporated, and who shall be registered under the provisions of this Act, shall be members of the said Society.

4. There shall be a Council of Management of the said Society, to be appointed in the manner provided for in this Act, and hereinafter referred to as "the Council."

5. The Council shall be composed of twenty-one persons, who shall, in the first instance, and as a Provisional Council, consist of the present Council of the existing Canadian Society of Civil Engineers, if British subjects and residing within the Dominion of Canada.

6. The members of the said Provisional Council shall meet in the City of Winnipeg for the purpose of organization, within two months after the passing of this Act, at such time and place as may be set forth in a notice in the Manitoba Gazette, and at such meeting any five members of the Council shall form a quorum.

7. A general meeting of the members of the Society shall be called by the Provisional Council, on or before the First day of February next after the passing of this Act, for the election of a permanent Council. The time and place for such meeting shall be determined by the Provisional Council, and at least two weeks' notice in writing shall be given by the Secretary to each member of the Society, and such meeting and any subsequent meeting of the Society may be held without this Province, but in the Dominion of Canada, as the Council may from time to time determine.

8. All members of the permanent Council shall be elected by ballot, each member having one vote, and the member or members obtaining the greatest number of votes shall be declared elected.

9. The members of the Council so elected shall hold office for the following terms respectively:

The seven names who have received the greatest number of votes shall hold office for the term of three years, the next seven names for the term of two years, and the third and last seven names for the term of one year.

10. No person shall be eligible for election to the Council, or qualified to fill any vacancy therein, or to vote for any member thereof at the first election, unless at such time he shall be a duly qualified member of the said existing Canadian Society of Civil Engineers; and no person shall be eligible for election to the Council, or qualified to fill any vacancy therein, or to vote for any member thereof at any subsequent election unless duly qualified under the provisions of this Act and the By-laws of the Society.

11. In the case of the death or resignation of any members of the Council, the other members of the Council shall have power to fill all vacancies so caused until the time of the holding of the next annual meeting.

12. Meetings of the Society and Council shall be held at such times and places as may be fixed by by-law of the Society, and at all meetings of the Society or Council the President or Chairman for the time being shall have a casting vote.

13. The Council shall have full power to enact by-laws for:

(a.) The qualification, election and registration of members of the Society.

(b.) The appointment and removal and defining the functions and duties of all officers and servants of the Society, and their remuneration, the time and place of holding meetings of the Society and Council, and the notice to be given therefor.

(c.) The calling of all meetings, the quorum and the procedure in all things at such meetings.

(d.) The suspension, expulsion, disciplining and readmission of members.

(e.) The appointment of examiners for the purpose of ascertaining and reporting upon the qualifications of persons who shall present themselves for admission and enrolment as students at any examination.

(f.) The admission and regulation of students, the periods and conditions of study, and all matters relating to the discipline and honor of the profession.

(g.) The regulating and fixing of the admission and annual fees payable by members and students. And to deal with and regulate all other matters necessary for the government of the Society, and to effectually carry out its objects, and generally to administer the affairs of the Society.

14. The Council may from time to time repeal, amend and re-enact the by-laws of the Society; but every such by-law and every repeal, amendment and re-enactment thereof, unless in the meantime confirmed at a General Meeting of the Society, duly called for that purpose, shall only have force until the next Annual Meeting of the Society, and in default of confirmation thereat, shall, at and from that time only, cease to have force, and in that case no new by-law to the same or like effect shall have any force until confirmation at a General Meeting of the Society.

15. The Council shall cause to be kept by an officer appointed by it, to be called the Registrar, a book or register, in which shall be entered the name of every person registered as a member of the Society, according to the provisions of this Act, and those persons only whose names are inscribed in the book or register above mentioned shall be deemed to be members of the Society, and such book or register shall at all reasonable times be open for inspection by any member of the Society of by any other person.

16. If the Registrar shall wilfully make or cause to be made any falsification in any matter relating to the register, or shall refuse to allow the register to be inspected, he shall be deemed to be guilty of a misdemeanor, and shall on conviction thereof be imprisoned for any term not exceeding twelve months.

17. On and after the 1st day of July, 1896, no person shall be entitled within this Province to take or use the name and title of "Civil Engineer" or any abbreviation thereof, either alone or in combination with any other word or words, or any name, title or description implying that he is a member of the said Society of Civil Engineers, or act as Engineer in laying out, advising on, constructing or superintending the construction of any railway or public work, or any work upon which public money is expended, the cost of which shall exceed $500, unless such person is a member of the Society hereby incorporated and registered as such under the provisions of this Act, or unless he is a duly qualified Civil Engineer, and entitled to use the title of Civil Engineer by virtue of some statute in force in this Province, or by the authority of some institution of learning in this Province having authority to confer degrees in Civil Engineering, or unless he has been practising as a Civil Engineer in this Province at the time of the passing of this Act, or unless he is a member in good standing of some institution of Civil Engineers in Great Britain and Ireland, or of some National Society of Civil Engineers of good standing in any foreign country.

18. This Act shall be deemed a Public Act.

◆

THE PUBLIC AND PRIVATE DEBT OF THE UNITED STATES.

Among the publications of the Department of Labor at Washington is a bi-monthly "Bulletin," containing current facts relating to the condition of labor in this and in other countries, and other information deemed of value to the industrial interests of the United States. It is edited by Labor Commissioner Carroll D. Wright and by his Chief Clerk, Mr. Oren W. Weaver.

A recent number of this bulletin treats of the public and private debt of the United States; a subject that is being discussed a good deal of late. The compiler of the bulletin explains by way of preface that it is practically impossible to show the private debts of the people, and even if it could be ascertained the result would be meaningless. A man may owe a large sum and yet have no burden of debt if an equal sum of money is owed to him. What is of interest is to know the debt that must be paid, not by payments of other debtors, but by the fruits of industry and economy. The following statistics, therefore, show these debts, which are offset little, if any, by credits. All except 12.14% of the items used are taken from the census returns of 1890 and are supposed to represent the minimum debt at that time.

Somewhat condensed from the tables given the statement stands as follows:

Steam railways, funded and unfunded debt.		$5,669,431,114
Street railways, funded and unfunded debt.		*182,240,754
Quasi public corporations:		
Telephone companies	$4,992,565	
Telegraph companies	20,000,000	
Public water companies,**	80,127,489	
Gas companies	75,000,000	
Electric light and power	45,000,000	
Transportation companies, not otherwise specified, canals, turnpikes, bridges, etc.	114,208,078	
		348,328,132
Total		$6,200,000,000
Real estate mortgages		$6,019,679,985
Crop liens (estimated)		650,000,000
National banks, loans and overdrafts		1,904,167,351
Other banks, loans and overdrafts		1,172,918,415
National, State and local taxes		1,040,473,013
Other private debts (estimated)		1,212,761,236
Aggregate private debt		$18,200,000,000
Public debt, less sinking fund:		
United States	$891,960,104	
States	228,997,389	
Counties	145,048,045	
Municipalities	724,463,060	
School districts	36,701,948	
		2,027,170,546
Aggregate private and public debt		$20,227,170,546

---

*By table published in our issue of July 6, this item is now about $600,000,000.

**Not owned by cities.

In the above the debts of individuals and private corporations amount to 59.33% of the total, and quasi-public corporations form 30.65%. The real estate mortgage debt alone is 29.76% of the total, and the railway companies follow with 28.03%. The public debt of the United States forms 4.41% of the total as compared with 3.58% for municipalities. The author places the wealth of the United States, in 1890, at $65,037,091,197; so that the total private and public debt represents 31.10% of the total wealth of the country. The per capita private debt, in 1890, was $291, and public debt $32, an aggregate of $323, or $15.94 per family of 4.93 persons. The real estate mortgage debt is $6,019,679,985; while the estimated value of taxed real estate and untaxed mines was $36,025,071,490.

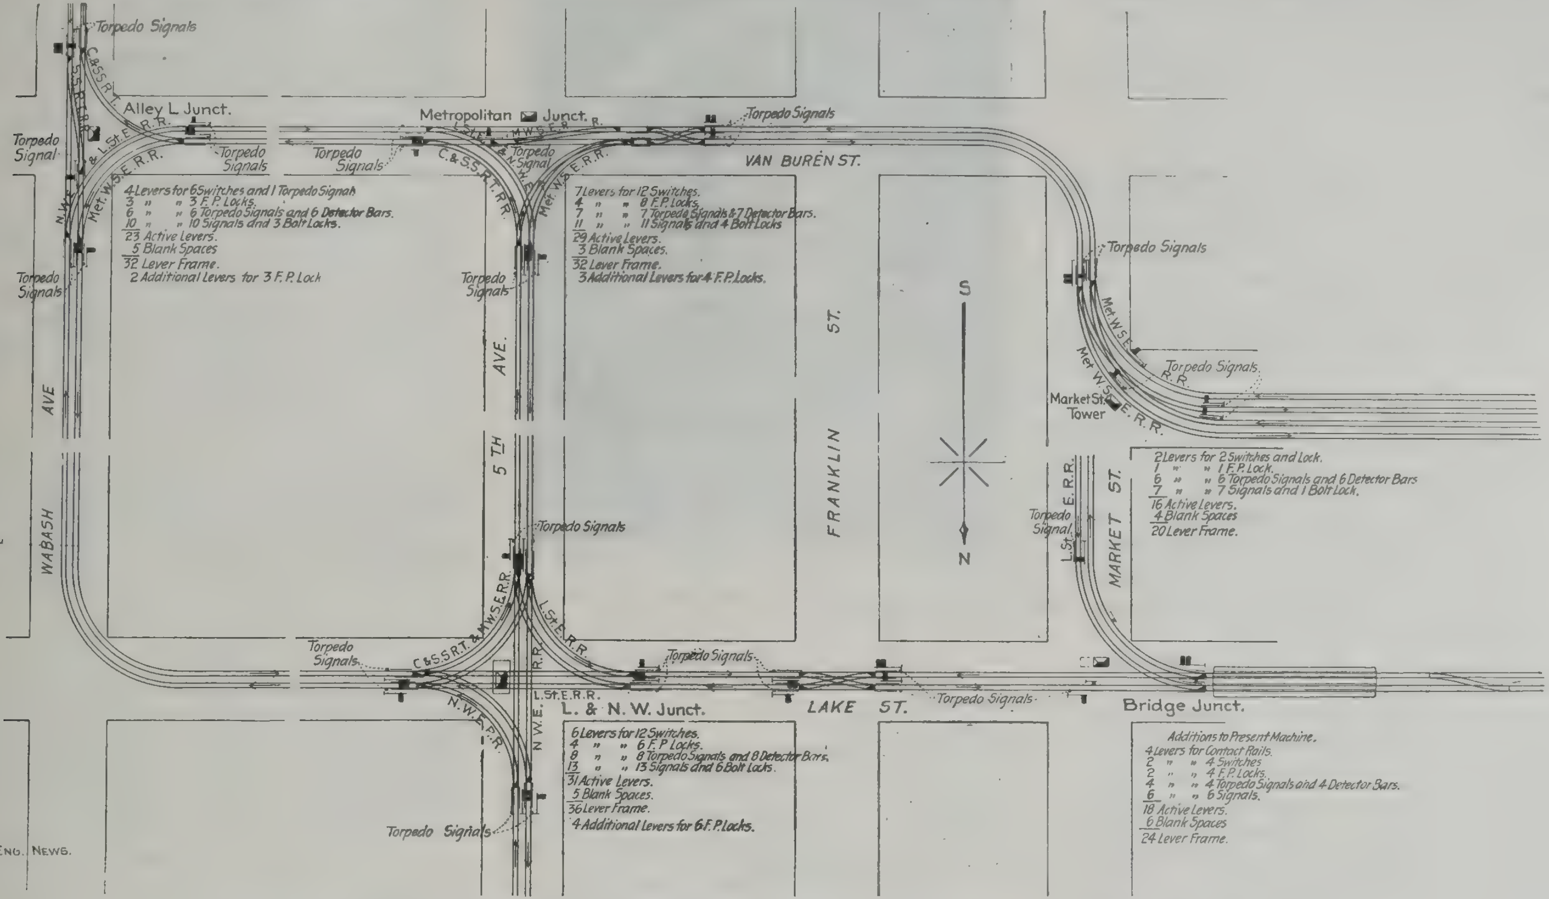
◆

SIGNAL AND INTERLOCKING PLANT FOR A LOOP TERMINAL AT CHICAGO; UNION ELEVATED RAILWAY.

The city of Chicago has now a number of elevated railways extending in all directions from the central part of the city, and work is now in progress on a loop terminal system which will connect the several lines, and enable them to land passengers in the heart of the business district, as described and illustrated in our issue of July 16. This line is being built by the Union Elevated Ry. Co., which has been formed by representatives of the Chicago & South Side Elevated Ry. Co. (Alley Line), the Metropolitan West Side Elevated Ry. Co., the Lake Street Elevated Ry. Co., and the North Side Elevated Ry. Co. The first three lines are in operation, and the fourth is preparing to build a line northward from Lake St. This loop line will be a double-track line, with junctions at Wabash Ave. and Van Buren St., Fifth Ave. and Van Buren St., and Lake and Van Buren Sts., together with the necessary connecting tracks, crossovers, etc. In addition to these three junctions, the four-track line of the Metropolitan Elevated Ry., which now ends at Franklin St., will be changed so as to carry traffic south on Market St. to Van Buren St., and the present interlocking plant at Bridge Junction will be enlarged so as to operate the double crossover at Franklin and Lake Sts. These junctions are indicated in the accompanying plan, which also shows the location of all switches and signals.

The volume of traffic which will be put upon the loop line will, it is said, probably exceed that of any railway now operated. The number of trains now on the three railways in operation is not less than 1,000 per day, and with the addition of trains from the North Side railway this traffic will probably not be less than 1,500 trains per day. On the three lines now in operation the trains are run on the right hand track, and in order that the traffic may be divided on the loop it has been decided to operate this loop left handed, the outer track being used by the North Side and the Lake St. lines, and the inner track by the Metropolitan and South Side lines. By following the current of traffic on the several lines, as indicated by the arrows on the plan, it will be seen that the crossings at the several points will necessitate the installation of a very complete system of signaling and interlocking in order that the maximum of safety may be secured with the minimum of delay in the manipulation of traffic.

All switches will be considered as facing point switches and will be equipped accordingly, and since it is not feasible on an elevated structure to provide any physical protection in the shape of a derail or scotch block, the torpedo machine will be installed and operated in the same manner as a derail and each signal will be operated in conjunction with this torpedo signal, all torpedo signals having separate levers, and connections from them operating the signal. The introduction of this audible signal will undoubtedly prove of great value in the operation of traffic over this complicated system of tracks, as it gives immediate notice not only to the engineman but to all train hands when the first pair of wheels has passed a home signal set at danger. Each torpedo machine is equipped with a certain number of detonators, and since the operator in charge of the plant is required to keep a complete record of the detonators delivered to him it is not likely that he will allow an engineman to pass a signal at danger and explode a detonator without making a full report to the proper officer. At the same time, as the engineman knows that such a report will be filed against him for disobeyance of signals, he will not be likely to pass a signal at danger.



SIGNAL AND INTERLOCKING PLANT FOR THE LOOP TERMINAL OF THE UNION ELEVATED RY. CO., CHICAGO.
National Switch & Signal Co., Easton, Pa., Engineers and Contractors.

The machine at Fifth Ave. and Lake St. will be located in a tower spanning the tracks and will have 40 levers; the machine at Wabash and Van Buren Sts. will be placed in a tower on the deck of the bridge and will contain 32 levers; the machine at Van Buren St. and Fifth Ave. will be located in a tower south of the south track and will contain 36 levers; the machine at Market and Franklin Sts. will be located in a tower between the lines of Franklin St. and will contain 20 levers; the additions to the present plant at Bridge Junction will involve 24 levers. All the signal towers will be of fireproof construction, and completely equipped with modern plumbing, heating and telephone connections. The machines will be carried on steel frames.

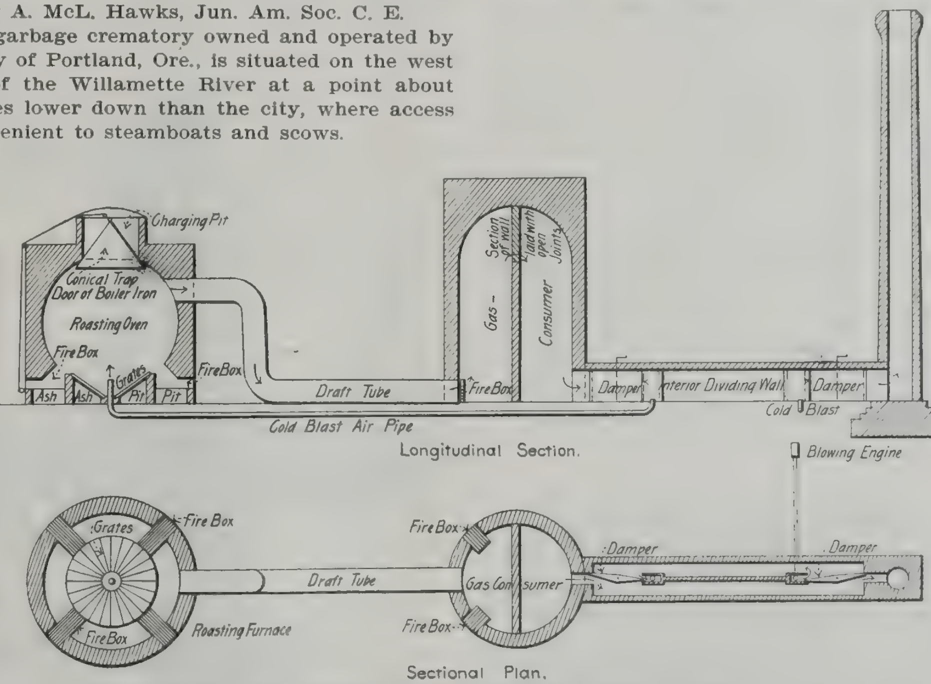
The operation of traffic around the loop will be entirely in the hands of the Union Elevated Ry., and as soon as a train from either of the four lines operated on the loop enters the limits of interlocking all trainmen will be under the orders of the officers of the loop. It is expected that work will be commenced at once at Bridge Junction and Van Buren St. and Fifth Ave., and be pushed to completion as soon as the structure is built on Van Buren St. The motive power to be used on the loop will be electricity, operated in the same way as on the Metropolitan West Side Ry., there being a third rail carrying the current which is supplied to the motor through a contact shoe which runs on this rail.

The contract for planning the entire system, and for designing and installing all the work, has been given to the National Switch & Signal Co., of Easton, Pa.; and the company was instructed by Mr. D. H. Louderbach, General Manager of the Union Elevated Ry., to present the most complete plans necessary for the safe and convenient handling of the traffic, without regard to cost of installation.

THE GARBAGE CREMATORY AT PORTLAND, ORE.*

By A. McL. Hawks, Jun. Am. Soc. C. E.

The garbage crematory owned and operated by the city of Portland, Ore., is situated on the west bank of the Willamette River at a point about 15 miles lower down than the city, where access is convenient to steamboats and scows.



SKETCH PLAN AND SECTION OF GARBAGE CREMATORY AT PORTLAND, ORE.

The building is a shed-like structure covering the furnaces, which are shown by the accompanying sketch, with a square stack 70 ft. high at the rear. The wharf, or landing, is two stories high, the lower story at the level of the furnaces and the upper at the level of the top of the main or roasting furnace.

The plant consists of a brick roasting furnace, circular in form, the oven of which is nearly the shape of a perfect sphere. At the four quadrants are fire-boxes penetrating to the oven. At the top is a large circular opening leading down to the oven; and to close this aperture is a conical bell of boiler iron hung by a chain over a pulley. At the bottom is a tuyere whereby a strong blast is brought into the oven at a point directly below the opening and between the four fire-boxes. On the side of the oven, well up towards the opening, is a 4-ft. circular draft tube of steel leading to the second or "gas consuming" furnace.

This secondary furnace is also of brick and circular in form, and is of a little greater height than the first or roasting furnace. The interior is cylindrical with a hemispherical dome at the top, and is divided in halves by a brick wall, the part included in the dome being laid with joints open very wide. On the side of the partition wall nearest the roasting furnace are two auxiliary fireboxes, one on each side of the draft tube for the purpose of assisting in burning the gases as they come over from the roaster. Later on the upper part of the partition wall was entirely removed, as it hindered the draft almost to the point of entirely stopping it.

---

*Information collected by Mr. Hawks for Mr. Rudolph Hering, M. Am. Soc. C. E., and published with the consent of Mr. Hering.

From the secondary furnace, or gas consumer, a long chamber leads to the stack, divided by a fire brick partition wall and dampers so the draft may be turned to either side of the chamber.

There is a small blowing engine for the purpose of furnishing a forced draft to the roasting oven.

The plant was constructed in March, 1894. The first change made was in the conical bell trapdoor of the roaster. Subjected to the great heat of the roasting oven, with the draft from the blast directly against it, it soon overheated and warped badly. It was replaced with a heavier one having a cast rim at the lower edge, which seems to stand well.

The next change was the removal of the upper part of the partition wall in the gas consumer. Although the joints had been laid dry and very wide open, the soot and grease soon began to collect in the narrow crevices, hindering the draft to such an extent that finally the capacity of the furnace fell below the requirements, and the top of the wall was taken down. Before that time the plant had been entirely successful in the attainment of the objects sought. No odor from the furnace could be detected at that time.

When I visited the plant recently, it was in full operation. The garbage is dumped at the dock in Portland into boxes about the size and shape of the body of a large dump cart. These boxes are taken, on a scow, to the wharf of the crematory, where they are hoisted to the upper landing directly beside the charging pit. At intervals determined by the condition of the furnace, this pit is filled and then the bell is lowered, permitting the load to slide off evenly distributed all over the oven. The size of the charging pit is great enough to permit whole animals to be passed through.

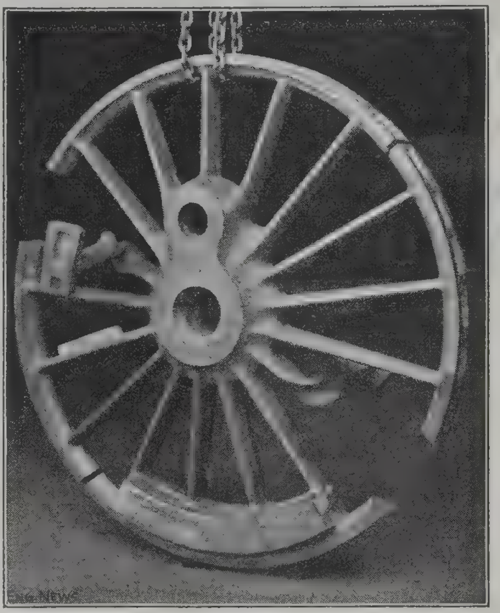
On the leeward side of the furnace there was a distinct odor which could be observed over a fan-like area having the stack for a centre and being 200 to 300 ft. wide at a distance of 500 or 600 ft. Beyond that distance it was so faint that it could not be determined. On breezy days it is said to be observable at 1,000 ft. distant. As the crematory is removed from any settlement, and no houses are near, there has been no complaint. The fires in the furnaces are continuous and the plant consumed 35 tons of garbage per day, using two to three cords of wood in the fire-boxes for aiding in the cremation. Five men are employed.

The ash from the roasting oven is perfectly odorless and inert. It can be sold as a fertilizer, bringing $10 per ton. The garbage is not sorted, so this is the only source of revenue. No account has been kept whereby the reduction of weights can be ascertained; the opinion seems to be that it takes about ten tons of garbage to make one of ash. The odor from the stack in its present operation is not exceedingly offensive, somewhat resembling cooking ham. If the city makes no other change it is probable that the partition wall will be again built up in a modified form.

A CAST-STEEL DRIVING WHEEL CENTER.

It is not so very long ago that cast iron was deemed a good enough material for driving wheel centers. The last dozen years, however, have brought increased train speeds, greater loads per wheel, more powerful locomotives, and driving wheels of larger diameter. Under these conditions it is found that the best metal available is none too good for driving wheel centers, and the best quality of cast steel is now extensively used for this purpose.

The accompanying cut shows what remarkably tough and ductile material is now obtainable in cast steel, and also that the steel founder does not hesitate nowadays to undertake castings of complicated form. The casting shown is a driving wheel center 72 ins. in diameter for a 78-in. driving wheel. The axle is 8½ ins. in diameter and the crank-pin is 5½ ins.. The total weight of the casting is 2,795 lbs., which is, we understand, about 500 to 700 lbs. less than the weights of cast-iron centers of the same diameter.



Cast-Steel Driving Wheel Center for 78-in. Wheel. Made by the American Steel Casting Co., Thurlow, Pa.

The casting was made from open-hearth steel with the following physical characteristics:

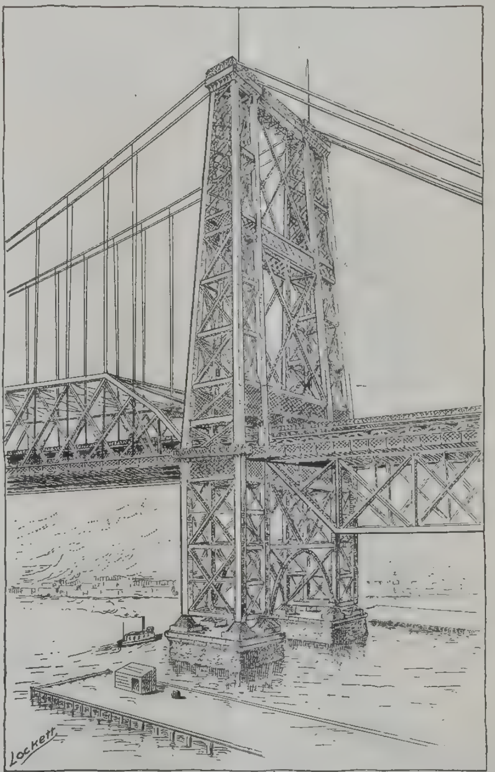
Ultimate tensile strength, 68,500 lbs.
Elongation, 28.50%.
Reduction of area, 47%.

It was cast by the American Steel Casting Co., of Thurlow, Pa., and the managers of that company inform us that about 2,500 to 3,000 wheels equipped with these centers are in service and are giving entire satisfaction.

The casting from which our photograph is taken was exhibited at the recent Saratoga convention of the Master Mechanics' Association.

THE TOWERS FOR THE NEW EAST RIVER BRIDGE.

As the result of some criticism upon the general design of the New East River Bridge, from an aesthetical point of view, and of an effort to associate a competent architect with the civil engineer in this design, Chief Engineer L. L. Buck submits the accompanying perspective view of the tower as designed by him.



Perspective View of Towers Designed for the New East River Bridge.

From a purely structural standpoint this design doubtless answers every requirement; and in criticising the design the elements of mass and height must not be neglected. We are utterly opposed to false ornamentation in similar structures and to any attempt to disguise the real materials of construction or the chief lines of stress. But in a monumental work of this character, in the center of a great city, good taste in design and proper ornamentation must be considered; and if a more pleasing effect can be secured without sacrificing the elements above referred to, the effort should certainly be made and is worth the added cost.

LEGAL DECISIONS OF INTEREST TO ENGINEERS.

When Municipal Consent is Necessary for Operation of City Railway

Municipal consent is requisite to enable any railroad company, whether incorporated by special act of assembly or under general railway laws of a state, to enter upon and occupy the public highway of the city, unless its charter contains authority for same in express terms or by necessary implication.—Philadelphia v. River Front Ry. Co. (Supr. Ct. of Penn.) 34 At. Rep., 60.

Injunction Against Water Company.

Where the water furnished by a water company, incorporated under the laws of Pennsylvania, for the use of the inhabitants of a town in that state, is utterly unfit for domestic use, or use by domestic animals, and is so destructive to pipes and boiler flues as to be unsafe for steam purposes, it is proper to enjoin such company from collecting water rents for other purposes than for extinguishing fires and flushing sewers.—Brymer v. Butler Water Co. (Supr. Ct. of Penn.), 33 At. Rep., 707.

City Liable for Damage to Property in Grading Streets.

Under a constitutional provision that no person's property shall be taken, "damaged" or destroyed for or applied to a public use without adequate compensation being made, where a city in grading streets, leaves large and dangerous holes in the streets, and also in the abutting lots, it is liable to the owners of such lots for damages, if any, to the lots; and the measure of damages is the market value of the lots immediately before and immediately after the excavations were made.—San Antonio v. Mullaly (Ct. Civ. App. of Tex.), 33 S. W. Rep., 256.

Forfeiture of Charter of Water Companies.

The failure of a water company to elect directors or officers, or to hold any meetings, or to perform any corporate act, for many years, and an attempt to sell and surrender all its property to another corporation, is a wilful violation of corporate duties, entitling the state to demand a forfeiture of its charter. The fact that another company is furnishing the people with water, as the pretended successor to such company, will not deprive the state of the right to demand a forfeiture.—City Water Co. v. State (Ct. Civ. App. of Tex.), 33 S. W. Rep., 250.

Street Railway Liable for Entire Street Paving.

The charter of a street-car company provided that it should be compelled to keep in constant repair that portion of the street which it uses and occupies and be subject to such ordinances of the city council as relate thereto; and the city ordinances provided that all street car companies should be at the entire cost and expense of maintaining, paving and repairing that may be necessary on any street occupied by them. The Supreme Court of Pennsylvania held that such company was bound to keep in repair not only the portion of the street occupied by them, but the whole street from curb to curb.—Philadelphia v. Passenger Ry. Co., 33 At. Rep., 126.

Liability of Director of Mining Corporation.

The law of California declares it the duty of the mine superintendent to file weekly and monthly accounts and reports, verified under oath, showing receipts, disbursements, number of employees, and wages paid, reports to be kept in the office of the company, open to inspection of the stockholders. It further provides that in case of the failure of the directors to have the reports and accounts made and posted as provided, an action shall be liable by any stockholder, who, on proof of the failure, shall recover judgment for $1,000 liquidated damages. The Supreme Court of that state held that, the statute being remedial, and there being no ambiguity in it, recovery could be had of the directors for failure to have the accounts and reports of the superintendent verified by him, though they were full, true and correct, and there was no one within many miles of the mine who could administer oaths, and the directors acted in good faith, and had been advised by counsel that it was not necessary to have them verified. Under such statute, it is not necessary to prove damages. They will be implied from its violation.—Shanklin v. Gray, 43 Pac. Rep., 399.

Elevated Railways and Damages to Abutting Property.

The New York Court of Appeals recently said: The elevated railroad companies are entitled to receive from the courts ample protection in view of the numerous actions they are called upon to defend, and the vast amounts involved in their determination, and judgments against them ought not to be upheld resting upon mere speculation unsupported by evidence; but, on the other hand, parties whose property may have experienced a small advance in fee and rental values since the completion of the elevated road ought not to be remediless when all the facts render it clear that property along the line of such road has been damaged by the interference with the easements of light, air and access, and has for that reason failed to share the advance in values of adjacent property, manifestly due not only to the construction of the elevated system, but to that natural growth which the neighborhood would have experienced by reason of the increase of population and business in a great city, even if the railroad had never been constructed.—Malcolm v. New York El. Ry. Co., 41 N. E. Rep., 793.

Payments to Contractors for Public Buildings.

Where the legislature required that a contract for the erection of a public building should be let to the lowest bidder, but limited the cost, and the contract was let to one who bid less than the amount of appropriation, but afterwards contracted with the commissioners having charge to make some alterations for which he was to look to the state for the additional cost, the difference between the sum bid and the amount of the appropriation cannot be recovered, as such additional contract was not binding on the state, because not let in manner prescribed by law. —Nichols v. State (Ct. Civ. App. of Tex.) 32 S. W. Rep., 452.

Admissibility of Record of Surveys.

The record of a survey by a county surveyor in subdividing a section which neither shows for whom the survey was made, nor the variation of the magnetic needle from the true meridian, as required by the laws of Michigan, and which does not purport to fix definitely the center of the section, is not admissible in evidence.

And though the laws of that state provide that the certificate of the county surveyor of any survey made by him shall be presumptive evidence of the facts therein stated, yet when other surveys made by competent surveyors are introduced in evidence the survey of the county surveyor is of no more binding force than the others.—Van Der Groef v. Jones (Supr. Ct. of Mich.) 65 N. W. Rep., 602.

Civil Engineer Has a Lien.

A civil engineer who makes field notes, maps, charts and drawings, while employed by a corporation in and about the construction of an irrigating canal, on books and papers furnished by the corporation, is entitled to a lien on such field notes, maps, charts and drawings, and has a right to retain possession of the same until he is paid for making them. It does not make any difference whether he was employed by the day or the month, or whether he was employed to make the field notes, etc. —Amazon Irrigating Co. v. Briesen, 41 Pac. Rep., 1119.

Appliances on Electric Street Railways.

An electric street railway is not required to have in use the latest improvements which have been devised to prevent collision with vehicles and pedestrians, but only to use reasonable care to avail itself of new inventions and improvements known to it.—Richmond Ry. & Elec. Co. v. Gartright (Sup. Ct. App. of Va.) 24 S. E. Rep., 267.

Recovery of Excessive Charge from Gas Company.

Where an ordinance provides that a gas company shall not charge consumers more than a certain rate, payment by a private consumer of a charge in excess of such rate may be recovered, though no right of action in his favor is given by the ordinance.—Pingree v. Mutual Gas Co. (Supr. Ct. of Mich.) N. W. Rep., 61.

Construction Company Liable for Neglect of Foreman.

Whenever the nature and magnitude of an undertaking, whether it be of construction or otherwise, are such that it is necessary that orders be given regulating the conduct of employees, and directing them where to work, it is not only the right, but the absolute duty of the employer of such men to give the orders; and in obeying such orders the employees have a right to assume that he has exercised due care for their safety; and where the orders are given by a foreman, who has authority to employ and discharge such men, the foreman is a vice principal, and the employer himself is liable for the negligence of the foreman.—Carlson v. N. W. Tel. Exch. Co. (Supr. Ct. of Minn.), 65 N. W. Rep., 915.

Injunction Will Not Lie Against Sewer Construction.

Where a village constructs a sewer that empties the village sewage into a natural water course outside of the village limits, the owner of the lands across which such water course runs cannot enjoin the construction and use of such drain, unless it is proved to be a nuisance. The dismissal of such a bill should be without prejudice, as the sewer may become a nuisance afterwards.—Robb v. Village of La Grange (Supr. Ct. of Ill.) 42 N. E. Rep., 77.

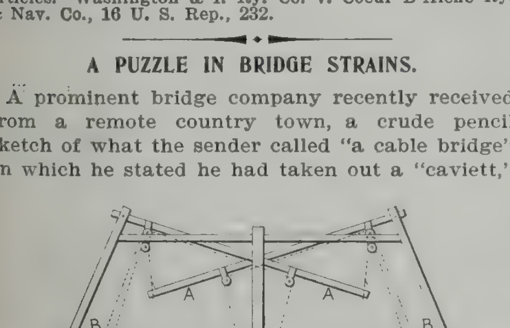
Railway Ownership of Surveyed Routes.

The Supreme Court of the United States holds that a company which surveys a line over public lands beyond the termini fixed by its charter, and afterwards files supplemental articles of incorporation authorizing an extension covering the survey, acquires no right of way beyond such termini, under the laws of the United States, as against another company which, having full powers, makes a survey over the same land after the other company's survey, but before the filing of its supplemental articles.—Washington & I. Ry. Co. v. Coeur D'Alene Ry. & Nav. Co., 16 U. S. Rep., 232.

◆

A PUZZLE IN BRIDGE STRAINS.

A prominent bridge company recently received from a remote country town, a crude pencil sketch of what the sender called "a cable bridge" on which he stated he had taken out a "caviett," and was desirous of selling his rights. The pencil sketch has come into our hands, and it is so curious an affair that we have thought it worth while to resketch it, so as to put it into a shape that may be understood, and submit it to our readers. The task of computing the strains in the various members of this funicular absurdity may prove an agreeable pastime to while away an hour in some of these hot summer days. The only legends attached to the sketch to aid in understanding the construction are one to the effect that "butman (abutment!) lever B works on pivot" and lever A "lifts and distributes strain." We are indebted to Mr. Geo. E. Gifford, M. Am. Soc. C. E., for the original sketch, from which our own is prepared.



"A Cable Bridge."

FIG. 1.—METHOD OF ATTACHING PLANKING TO STRINGERS IN CONSTRUCTING UNDER WATER MOLDS FOR CONCRETE WALLS OF HERR ISLAND DAM.

◆◆

THE FOUNDATIONS OF THE HERR ISLAND LOCK AND DAM, NEAR PITTSBURG, PA.

In the Annual Report of the Chief of Engineers, for 1895, Major R. L. Hoxie, Corps of Engineers, U. S. A., describes the preliminary work for the foundation of the movable dam at Herr Island, near Pittsburg, Pa. This dam is to be a part of a system of slackwater navigation on the Allegheny River, and is also intended to enlarge the harbor room at Pittsburg by forming a pool. The dam is to be of the movable type, and the estimated cost, on the plans approved July 10, 1894, is $600,000.

It was originally planned to enclose the side of the lock and dam within a coffer dam, and work was commenced upon that basis. But on attempting to pump out the enclosure it was found that water came in in large quantities, not only under the dam, but from springs in the bottom, and all attempts to close these by dumping clay and gravel were a failure. The area enclosed by the dam was about 600 by 200 ft., or about three acres of river bottom. The deposit of sand and gravel overlying the rock was about 35 ft. thick, the rock being 45 ft. below the water level, while the plans required an excavation 20 ft. deep below this water surface. The bottom deposit had been worked over for years by sand-diggers who threw back the large stones and coarse gravel after removing the fine sand; this work resulting in a very permeable bottom, with possible channels of comparatively large dimensions extending to unknown distances beyond the limits of the coffer dam.

Under these conditions Major Hoxie deemed the further trial of a coffer dam impracticable, and concluded that the foundation must be laid under water. He now proposed to dredge out the site of the lock to a point 30 ft. below the pool level, and to then drive piles and to these attach plank formers for confining a thick bed of concrete deposited under water and covering the entire area. Upon this concrete foundation walls of the same material would be built up until the weight of these walls and the redeposited sand and gravel between them would be sufficient to balance the head of water to be dealt with in completing the work from this point within coffer dams. All rupturing strains on the floor of the pumped-out lock-chamber would be met by the thickness given to the concrete bed.

This modified plan was approved on Sept. 6, 1894, and a contract for dredging was awarded to the Drake & Stratton Co., of Pittsburg, Pa. At the date of the report, June 30, 1895, the dredging was completed, the encircling piles were driven and divers were putting the concrete forms in place. In connection with this latter work, various somewhat novel appliances were used, and these are here described and illustrated, as taken from the report of Mr. J. W. Arras, one of the assistant engineers in immediate charge:

The piles were 40 ft. long and driven in 30 ft. of water; they were weighted at the lower end and hung from a staple in the upper end from the leads of the pile-driver; then lowered, accurately fixed in position by intersecting transit lines and driven, with 2 ft. of each pile extending above the surface after driving. They were afterwards spaced and approximately aligned by spiking temporary wale pieces upon them at the water surface. The bottom stringers, each 4 × 6 ins., and 12 ft. long, were attached to the inside of the piles by three 9-in. spikes in each pile; the upper stringer was in two pieces, one inside and the other outside, each piece 4 × 6 ins., and 20 ft. long, with the 6-in. dimensions horizontal, and they were bolted together with three ¾-in. iron bolts. These top stringers were framed together at the surface of the water, then lowered to position and the nuts on the bolts were finally tightened up by divers working from a platform suspended from the divers' boat. Each pair of stringers covered three piles, and the series overlapped one another at each third pile. A middle stringer was then put in place by divers working from a platform swung from the top stringers.

The 2 × 12-in. hemlock planks were placed vertically. Each plank, 20 ft. long, was put in position by divers, one stationed at the bottom and the other at the middle stringer. Workmen in a boat lowered each plank, with a gage-rod attached to its upper end weighted at the bottom, as shown in Fig. 1. When at the proper height the two divers nailed the plank to the two stringers, and the upper end of the plank, at a point 9 ft. below the surface, was nailed by means of a "shot-gun," which consisted of a hollow tube and sliding hammer, attached to a spike-pole for holding it in position. The spikes were fed down a second pipe when the hammer was partially withdrawn.

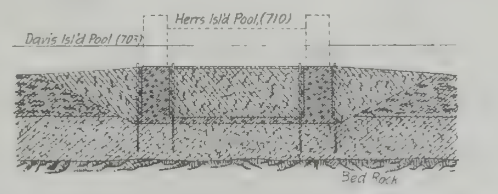

Fig. 2.—Concrete Foundation for Locks at Herr's Island Dam Completed and Ready for Supplemental Coffer Dam.

In this manner two parallel sets of piles and planking were placed in positions, at a sufficient distance apart to contain within them the concrete foundations for the lock-walls. The floor between these walls being first concreted, as shown in Fig. 2, and when the walls are carried up to a certain height the space between them and the outside of the foundations will be weighted with sand and gravel. Upon this filling coffer dams will be built and the remaining part of the lock-walls will be constructed within this dam.

EFFECT OF ENGINEERING WORKS ON WATER CURRENTS.

At a late meeting of the Canadian Society of Civil Engineers, Mr. Cyrus Carroll, C. E., read a paper upon the above subject, citing examples and cautioning engineers against designing structures without a previous careful study of existing conditions of water currents and prevailing winds.

As showing the effect of combined wind and current action he submitted maps of the several typical river-mouths here reproduced; and said that these maps fairly illustrate the existing conditions at the mouths of the Rivers Saugeen, North Sables, Penetangore, Pine, Maitland, Bayfield and nearly a dozen others named. These maps show sand-bars formed across the ends of the valley, as the result of opposing currents of river and lake meeting, sometimes fairly and squarely, but generally at an angle. These opposing currents join and form a new direction of current with an angle determined by their relative forces.

The sand-bar begins at the windward side of the valley and in time extends across it, crowding the river towards the leeward bank. As a consequence the channel is often narrow and deep when it crosses the bar, and the bar itself grows on the windward side by lake silt washed against it. The lake bank, below the river, is usually cut away.

Fig. 2 shows the utilization of one of these rivers as a harbor, by building out piers or jetties to deep water. They cannot always be entered in a storm; but vessels can seek the shelter of the lee side of the longer piers. Mr. Carroll strongly advises against attempts to form a new channel through the bar and cites Fig. 3 as an illustration of the effect of such a change in channel.

Lakes Burwell and Smith were once portions of Lake Huron; but in comparatively recent times they were cut off from the greater lake by sand dunes now extending out about four miles from the old shore of Lake Huron. Through these dunes the Aux Sables River reached the lakes by a very circuitous route. When the small lakes were first cut off by the dunes the river flowed northerly, as the dunes were extended in this direction by the action of the lake, and this continued until the nature of the shore at Grand Bend turned the river nearly due west. There the lake current opposed it from the northwest and a bar was formed which gradually forced the river close up along the foot of the sand dunes, and it took a general southwest direction, as shown. Had the river not been interfered with it would probably have reached Kettle Point, where the dunes ceased.

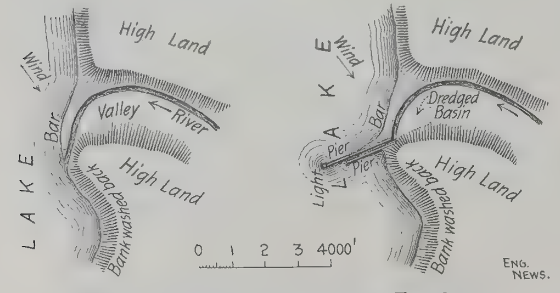

Fig. 1. Fig. 2.

Figs. 1 and 2.—Typical River Outlets on Lake Huron.

In 1872 a contract was let for the excavation of the Burwell Canal, which was intended to act as a drain to reclaim about 16,000 acres of land covered by these lakes. The canal cost about $80,000, and the result was disappointing. Lake Burwell lies about 4 ft. above Lake Huron, and as soon as a trench was made the water rushed out with such force as to excavate a channel about ⅛ mile wide. The great quantity of sand carried down stopped up the old mouth of the river and a new outlet was formed further north. New mouths were being continually formed as the old ones choked up from sand, and each one to the north of that preceding it. The general result was that only 1,000 acres of land was sold as reclaimed, and the regimen of the river was completely destroyed, spoiling it entirely for navigation purposes. Every freshet brings a new lot of sand for the river to work through as it may, and while Lake Burwell is dry in summer, Lake Smith still covers two-thirds of its former area. The old channel, between Grand Bend and Port Franks is filled up for considerable distances, and the lands near Grand Bend are subjected to more floods than ever before.

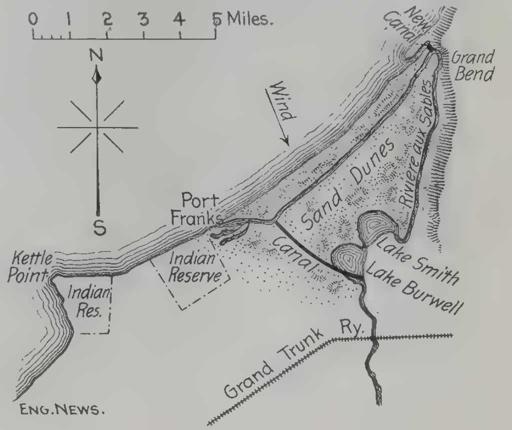

Fig. 3.—An Unwise Attempt at River Regulation.

In 1892 a new channel was cut through the beach at Grand Bend, at a cost of $21,500; but as soon as it was completed a beach began to form across the mouth and is now extending southward again along the base of the old dunes and parallel to the old channel, as shown in Fig. 3.

BOOK REVIEWS.

MODERN METHODS OF SEWAGE DISPOSAL for Towns, Public Institutions and Isolated Houses.—By Geo. E. Waring, Jr., M. Inst. C. E. Second Edition, Revised. New York: D. Van Nostrand Co. London: Sampson Low, Marston & Co. 12mo.; cloth; pp. 253; 22 illustrations; $2.

The first edition of this book was favorably noticed in our issue of Oct. 11, 1894. The only change which we can discover in the present edition is the re-writing of Chap. XIII., "Filtration with Aeration," so as to exclude all reference to other investigations of the subject and deal wholly with the author's experiments along this line at Newport. A footnote to p. 147 states that a report describing these experiments in detail "will be sent, without cost, to readers who desire it, upon application to the author at Newport, R. I.," so, obviously, no one who has the first edition need buy the second on account of the changes noted. The original edition, having been published before the Newport experiments were made, contained no reference to them, but interesting as they are it seems a pity to have sacrificed all the matter relating to other researches on the subject in order to have more space for the Newport studies, especially when the report named is available for all interested in the matter.

ELECTRIC LIGHTING.—A Practical Exposition of the Art, for the Use of Engineers, Students and others interested in the Installation or Operation of Electrical Plants. Vol. I, The Generating Plant. By Francis B. Crocker, E. M., Ph. D., Professor of Electrical Engineering in Columbia University. New York: D. Van Nostrand Co.; London: E. & F. N. Spon. 8vo.; pp. 444. $3.00.

The development of electric lighting until quite recently has been so rapid that any complete treatise on the subject would become out of date while it was being printed. At the present time, however, in the opinion of the author of the work before us, electric lighting has reached a sufficiently perfected and established state to allow of its being treated in a fairly satisfactory and permanent manner. The apparatus and methods employed are almost as well standardized as in other arts. The dynamo is one of the most perfect machines in existence. Arc and incandescent lamps, overhead and underground wires, transformers, and almost all the other parts of electric lighting plants have also become sufficiently stereotyped. The plan adopted in this work is to follow the sequence in which the electric current is generated, transmitted and utilized. The present volume treats of the generation of electric current, including location of plant, buildings, steam boilers and engines; gas, oil and hot-air engines; water-wheels and windmills; direct coupling, belting and shafting; principles, construction and management of dynamos; accumulators, switchboards, electrical measuring apparatus and lightning arresters. The transmission and utilization of the current for lighting purposes, together with descriptions of typical electric lighting plants, are reserved for the second volume. The first two chapters treat very briefly of the advantages of electric lighting and of its history, then follows a short chapter on general units and measures, in which are given the definitions of the "international" volt, ampere, etc., as given in an act of Congress in 1894, and now universally adopted, together with the specifications prescribed by the National Academy of Sciences for the practical determination of the ampere and volt. The present work differs from nearly all other works on electrical subjects in not devoting any space to discusion of the elementary principles of electricity, the reader being recommended to acquire a general knowledge of these principles from other works before undertaking the study of a special branch, such as electric lighting. The location and general arrangement of electric lighting plants, buildings, foundations, etc., are treated in his brief, but well written chapters. A discussion of the possible sources of electrical energy follows, in which the author states that the possibility of generating electricity directly from the combustion of coal more cheaply than by present methods is not encouraging. The hope of a new method by which electricity can be gotten directly from fuel-energy is very indefinite at present. It may be realized in one year, or perhaps not for a hundred, or even a thousand years. The steam-engine, history and general principles, is the heading of a chapter of only six pages. The book might be improved by leaving out this chapter altogether, or by considerably enlarging it and making it more clear to the general reader. We do not see why the formula $p\ v = R\ T$ is given on p. 92, when it is not stated what R means, nor why the differential formulas for isothermal and adiabatic expansion are given on p. 93, when the much more useful, practical formulas for calculating the work done in an engine cylinder are omitted. The chapter on steam-boilers covers 32 pages, and is fairly good. In the table of heating powers of coal, p. 94, bituminous is given as 8,000 centigrade heat units. A more correct statement would be from 5,000 to 7,500 heat units, as there is probably no bituminous coal in this country (semi-bituminous coals excepted) which have a heat value of 8,000 heat units. Writers of text books should make a clear distinction between the semi-bituminous coals, such as Cumberland and Pocahontas, which have a heating value higher than anthracite, and bituminous coals containing 30% and upwards of volatile matter, which have a much lower heating value. The author's statements that the use of a poor quality of coal on account of cheapness is usually bad economy, and that a larger boiler is required with poor coal to produce a given amount of steam, are far from being generally true. A poor quality of coal is often found in some markets to have a price much lower than that due to its quality, and in such cases great economy is often effected by its use. A poor coal usually requires a larger grate surface than a good coal, the use of shaking grates instead of plain grates, or the use of forced instead of natural draft, but not necessarily a larger boiler. The size of boiler required depends upon the amount of water to be evaporated, and not upon the quality of coal. The chapters on steam-engine construction, typical forms, selection, installation and management, on gas, oil and hot-air engines, and on water-wheels and windmills, occupy 100 pages of the book, and contain much information which may be useful to electrical engineers and others interested in electric lighting plants. The chapters on mechanical connections between engines and dynamos, and on toothed, friction and other gearing, are also excellent.

The strictly electrical portion of the work begins on p. 265 with a chapter on principles and construction of dynamos, which occupies 56 pages. In it is condensed a great quantity of useful information, although it is neither sufficiently elementary in its method of treatment to be read with satisfaction by those not already possessed of a considerable knowledge of the subject, nor complete enough to take the place of other treatises. Typical forms of dynamos for electric lighting are described in a brief chapter of 19 pages, which properly includes only the well-known modern forms. The practical management of dynamos occupies another short chapter, the reader being referred to another work for more complete treatment. Two chapters, covering 40 pages, are devoted to accumulators, their principles, construction, management and applications. The treatment of these subjects is quite satisfactory. Three brief chapters on switchboards, including switches, fuses and circuit-breakers, electrical measuring instruments, and lightning arresters, conclude the volume.

On the whole the book is about as satisfactory a one as can be expected, when its necessary limitations of space and price are considered; in other words, the field attempted to be covered is so vast and has such a variety of detail in every part of it that it is scarcely possible to do it justice in the narrow compass of a $3 book of 444 pages. Prof. Crocker has done as well, within the prescribed limitations, as could be done probably by any writer on electrical subjects.

AND
AMERICAN RAILWAY JOURNAL.

Vol. XXXVI., No. 9.

TABLE OF CONTENTS.

ENGINEERING NEWS OF THE WEEK........129, 144
- The Cernavoda Bridge over the Danube River (illustrated)........ 130
- Standard Specifications for Steel; Association of American Steel Manufacturers (illustrated)...... 130
- The Water-Works of Colorado Springs and the Strickler Tunnel (with inset, illustrated)........ 131
- A Current Motor for Pumping Water (illustrated). 134
- Insulating Rails from Metal Ties and Metal Bridge Floors (illustrated)...... 135
- Basic Steel Rails........ 135
- Legal Decisions of Interest to Engineers......... 135
- The Sewers and Sewage Farms of Berlin (illustrated)...... 139
- A New Single-Acting Compound High-Speed Engine (illustrated)........ 141
- A Split Sleeve for Making Connections with Water Mains in Place (illustrated)........ 142
- Water Consumption Through Metered and Unmetered Taps at Lexington, Ky.......... 142
- A German System of Metal Stair Construction (illustrated)........ 142
- Impermeable Covering for Stone Arches.......... 143
- Book Reviews........ 144

EDITORIAL NOTES........ 136
- The Cernavoda Bridge over the Danube—The Necessity of Using Derailing Switches at Grade Crossings—Municipal Investigating Committees—The Decision of the Court in the Case between the Hilton Bridge Co. and the Superintendent of Public Works of New York State—Unification of Methods of Testing Structural Material in Europe.

EDITORIAL........ 137
- An Opportunity for an American Steel Rail Plant in Australia.

LETTERS TO THE EDITOR........138
- Steel Makers and Chemistry—A Device for Operating a Gate from a Distance by Hydraulic Power (illustrated)—The "Student" Grade of Membership in Engineering Societies—The Cutting of Water Pipe by Sand Jet at Leaks (illustrated).

THE AWARDS FOR THE MONTREAL BRIDGE PLANS called for by the Montreal Bridge Co., have at last been made. The first prize has been awarded to Mr. E. S. Shaw, of Boston, Mass., and the second prize to Mr. A. L. Bowman, of Roanoke, Va. The awards were made by Mr. Walter Shanley, and he called special attention to a plan submitted by Mr. J. W. Balet, of New York, which, though possessing peculiar merit did not comply with all the conditions of the advertisement, and could not be considered in awarding the prizes. The company has, however, awarded a special prize to Mr. Balet. The call for competitive plans for this bridge were made early in 1895, and the general plan was shown in our issue of Feb. 14, 1895, Mr. C. N. Armstrong, of Montreal, is the Managing Director of the bridge company.

◆

A TRACK ELEVATION ORDINANCE covering a portion of the lines of the Chicago & Western Indiana and the Pittsburg, Fort Wayne & Chicago railways in Chicago, is benig prepared by the Aldermanic Committee on Track Elevation, and will be submitted to those companies for action at an early date. The elevation will begin at 71st St., and extend north to 22d St. From 47th St. north the tracks of the two companies run side by side, and all work will be done in common. Altogether about 40 subways for crossing streets will be required. This is the latest of several attempts which have been made to secure action on the part of the Chicago & Western Indiana Co., and it is stated that it will be forced if the company does not come to an early voluntary agreement. The policy of this road toward the track elevation movement and the controlling position which it occupies were explained in Engineering News, Jan. 23, 1896. The city authorities are awaiting also the decision of the Supreme Court this fall in regard to the order compelling the Union Stock Yards Co. to tear up its tracks on 40th St. If the city loses in this fight the tracks will be ordered elevated from Halstead St. to the Illinois Central R. R. tracks at once. The Aldermanic Committee has prepared plans for this change which provides that the tracks be elevated 15½ ft. on a steel structure. No street will be closed, but a number of thoroughfares will be slightly depressed, as follows: Lake Ave., 3 ft.; Wentworth Ave., 2 ft.; Bissell St., 3 ft.; Wallace St., 3 ft.; Sherman St., 4 ft.; Union Ave., 6.5 ft. At Emerald Ave. the roadway is raised 2 ft., and at Halstead St. the tracks come down to grade again.

◆

BIDS FOR A NEW WATER SUPPLY FOR JERSEY City were received on Aug. 24 from the East Jersey Water Co. and the Rockaway & Hudson Water Co. The bids were for constructing new supply works and delivering water to the present distributing reservoirs by the million gallons, with an option of purchase of the works by the city. As was to be expected from the character of the specifications, no formal bids for filtering the present Passaic River supply were received. The bids for the gravity supply are given in the accompanying table, not including those from the East Jersey Water Co. for a supply through one 50,000,000-gallon pipe line, which was not in accordance with the specifications, which called for two or more when the full supply of 50,000,000 should be developed. Although informal, the one bid made for a filtered supply is given as of interest, but it must be remembered that it does not comply with the specifications. The United States Filtering & Purifying Co., of Philadelphia, offered to deliver filtered water to the present reservoirs at $20 for each 1,000,000 gallons up to 20; $23 for each between 20 and 30; $21 for each between 30 and 40; and $18 for each 1,000,000 gallons between 40,000,000 and 50,000,000. It would sell a 30,000,000-gallon plant, with pumps, boilers and conduits, for $1,300,000, and a 50,000,000-gallon plant for 1,918,000.

Bids for a New Water Supply for Jersey City.

Bidder.	Source of supply.	Prices for each 1,000,000 gallons.				Purchase price for works to supply.	
		1 to 20	20 to 30	30 to 40	40 to 50	35,000,000 galls. per day.	50,000,000 galls. per day.
Plan A, gravity to low service, 127 ft. elevation.

THE CAISSON FOR THE INTAKE CRIB of the northwest water supply tunnel at Chicago, Ill., was launched Aug. 19 by Fitzsimons & Connel, the contractors for the submarine section of the tunnel. This caisson is 112 ft. in diameter, with walls 20 ft. high. Altogether 750,000 ft. B. M. of timber and 93 tons of steel and iron will be used in its construction by the time it is ready for sinking. The location of the crib will be three miles from shore and it is expected that the sinking of the caisson and the masonry for the crib will be completed this year. The structure was designed by Mr. John Ericsson, Assistant City Engineer, under the direction of City Engineer L. B. Jackson.

◆

WATER FROM THE HARBOR for increasing the fire protection of Boston has been proposed from time to time. It is reported that the question is now to be investigated by a joint committee of aldermen and councilmen, who will visit a number of cities to study this and other matters related to fire departments. The Boston "Journal" comments editorially on the trip under the heading "Eight to One," or eight politicians and one expert," and asks, "could not eight experts and one politician learn more to the advantage of the Boston Fire Department?"

◆

THE CONSTRUCTION OF A SANITARY AND DRAINage Canal west from the Calumet district, at South Chicago, Ill., is again rumored. It is stated that the intention is to follow the survey made by the U. S. Engineers, some years ago, which is practically the route of the present "Sny" feeder to the Illinois & Michigan Canal. The cost is estimated at from $10,000,000 to $15,000,000, and the method of procedure will be to organize a sanitary district similar to that organized to construct the Chicago Drainage Canal and raise the money by tax levies and bond issues as provided by the sanitary district law of the state of Illinois. The large land owners in the Calumet district are said to be at the head of the project, and the opinion is expressed that the scheme is simply an attempt to boom land values and will never get beyond the paper stage. Furthermore, it is charged that the assessed valuation of the district cannot possibly provide the necessary money from bonds and taxes at the rates of issue allowed by the state laws.

◆

A COMBINED OUTLET SEWER AND GARBAGE chute has been built at Niagara Falls, N. Y. The sewer is of steel, about 30 ins. in diameter, and 220 ft. long, extending from a 24-in. sewer at Bath Ave., over and down the bluff, which is here nearly 200 ft. high, to the water's edge. The sewage and garbage was formerly discharged over the bank, but the construction of the Gorge Electric Ry., near the water line, made this practice undesirable, to say the least. Mr. W. W. Reed is city engineer of Niagara Falls and gave us the above information. Mr. John Mahar, of Tonawanda, was contractor for the work, which was done last May. Mr. Reed says the new outlet is giving satisfaction.

◆

GAS-ENGINE STREET CARS on the Luehrig system (Eng. News, Jan. 24, 1895) have been put in operation on the new Blackpool, St. Ann's & Lytham Tramway, of England, and are said to be the first cars to be operated by gas in that country. Each car has a two-cylinder Otto gas engine of 15 HP., and reservoirs holding a supply of gas for a run of eight miles. The gas is obtained from the town mains and compressed at the company's station, and the charging is done by means of an india-rubber pipe, occupying but about one minute. The track from Blackpool to St. Anne's is for the most part along a country road, and some rather steep grades are easily mounted, the cars running at a speed of eight miles an hour, though they are said to be capable of running 12 or 14 miles per hour. Each car carries 40 passengers. Cars on this system are in operation at Berlin, Dresden and Dessau, in Germany.

◆

THE HOLLAND SUBMARINE TORPEDO-BOAT, now being built for the U. S. Government at Baltimore, is nearly completed and her builders expect that she will be ready for her trial trip in September next. If she succeeds in meeting the requirements of the contract this boat may work as great a revolution in naval warfare as did the "Monitor."

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week was the derailment, on Aug. 22, of a westbound freight train, near Horse Plains, Mont., on the Northern Pacific R. R. As the train was passing over a high embankment the bank settled and slid out, throwing the train into the Clark's Fork River. Four trainmen were killed. It is supposed that an underlying quicksand bed caused the accident.——A rear collision of westbound freight trains, at Valencia, Pa., on the Pittsburg & Western Division of the Baltimore & Ohio R. R., Aug. 24, caused the fouling of the eastbound track by wreckage, and the limited express ran into the obstruction, the engine and two cars going over the bank and most of the cars being wrecked. About 20 persons were injured, four being fatally injured.

◆

A BOILER EXPLOSION occurred Aug. 19 on the works of the sewer in Rockland Park, Rochester, N. Y.; one man was fatally injured and several others more or less injured. ——The boiler of the steamer "Manitou," on Clark's Lake, at Jackson, Mich., exploded Aug. 20, but nobody was killed.——A boiler in the car shops of the Pennsylvania R. R., at Pavonia, N. J., exploded Aug. 21, and one man was badly hurt.

◆

A LOCOMOTIVE BOILER EXPLOSION occurred Aug. 16, on the Colorado Midland R. R., at Basalt, Colo. A switch engine was standing at the station when its boiler burst and two men were injured.

◆

AN EXPLOSION OF GUNPOWDER occurred at the works of the Tomnicken Powder Mfg. Co., at Derringer, Pa., Aug. 20, killing one man and injuring three others.

◆

A COLLISION WITH AN ICEBERG on the Atlantic Ocean, Aug. 19, caused the loss of the tramp steamer "Moldava," carrying coal from Cardiff, Wales, to Halifax, Nova Scotia. The ship struck about 4.30 p. m., during a heavy fog, and in a few hours the vessel went down. The crew took to the boats and were picked up by the "Circassia," of the Anchor Line.

◆

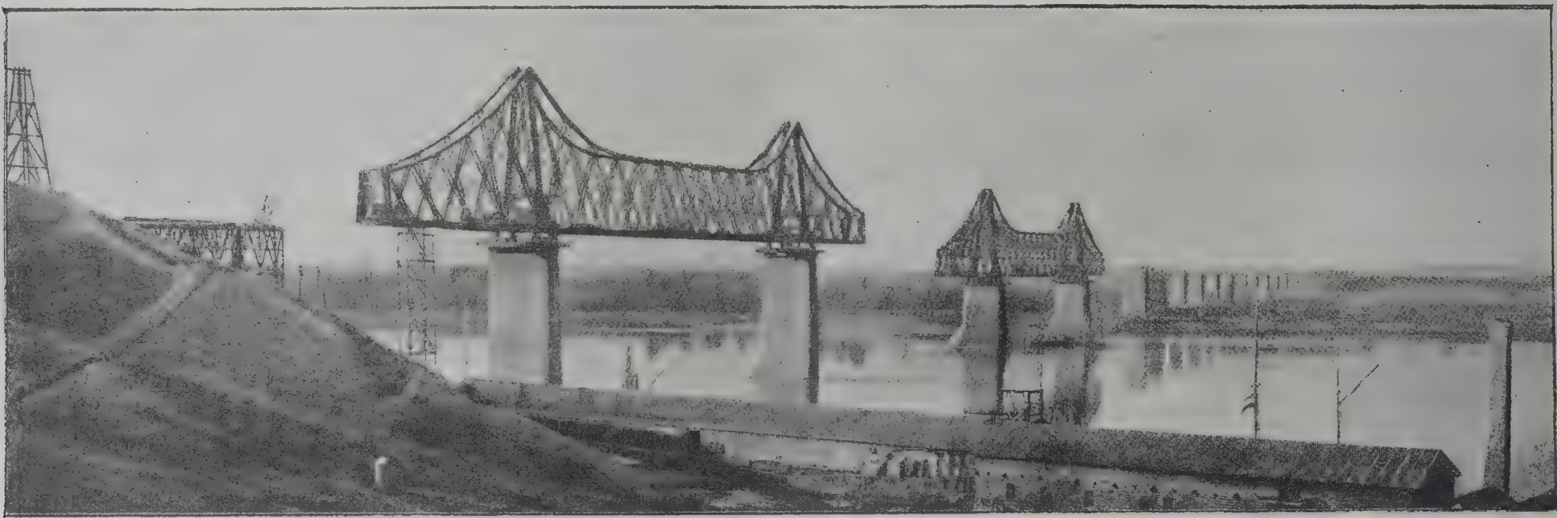
TWO MORE CASES OF RUNAWAY ELECTRIC CARS are reported: On Aug. 22 a car on the Bergen St. line of the Nassau Electric Co., Brooklyn, N. Y., got beyond control on the grade and left the track at the curve at the corner of Bergen and Hoyt Sts., running onto the sidewalk. Four of the eight persons in the car were slightly injured. The motorman said the brakes were out of order.——A car on the new line up the Catoctin Mountain, from Frederick, Md., to Braddock Height, got beyond control while coming down the grade, Aug. 23. The car crossed a high trestle and then jumped the track at a curve and fell over on its side. The car had seats for 45 persons but carried about 120 persons at the time, and about five persons were badly hurt, while some 30 more were cut and bruised. Passengers tried to put on the brakes but it is said they would not work.

◆

THE COLLAPSE OF A NEW FREIGHT SHED being built by the New York, New Haven & Hartford R. R., on Congress St., South Boston, Mass., occurred Aug. 19, by which one man was killed and ten were injured. The building was to be 1,000 × 60 ft., and about 600 ft. of its length had been built, and the wooden roof trusses were being put up at the time of the accident.

THE CERNAVODA BRIDGE OVER THE DANUBE RIVER.

The recent formal opening to traffic of the great bridge over the Danube in Roumania, after 5½ years spent in construction, has recalled the attention of engineers to a work possessing many features of unusual interest. It was in 1890 that the Roumanian government determined to undertake the bridging of the Danube, at Cernavoda, its purpose being to provide a direct route from the interior to the Black Sea. The Fetesti-Cernavoda Ry., whose track crosses the new structure, now gives an almost direct outlet to the ports on the Black Sea, and it is thought that the advantage thus gained will be felt especially in the transportation of agricultural products. At the point on the river where Cernavoda is located, and where it was determined to place the bridge, the Danube is divided into two branches by the island Balta. The river flows in a northerly direction at this point and it is the easterly channel that retains the name of Danube, the westerly being called the Borcea River. The island is swampy, and at certain times is entirely covered with water. It is between seven and eight miles in width. Two bridges are thus necessitated, and on the island a long stretch of embankment with an open viaduct about half way across. The total length of iron structure is about 13,460 ft., or 2.6 miles, this being divided as follows: Cernavoda bridge, 2,460 ft.; approaches to Cernavoda bridge, 3,000 ft.; viaduct on Balta island, 4,770 ft.; Borcea bridge, 1,380 ft.; and approaches to last named, 1,840 ft. The first two mentioned portions may be seen in the accompanying engraving, showing the Danube bridge in course of construction. The piers for the 15 spans of the approach lead away westward to the end of the embankment in the distance.



CANTILEVER BRIDGE OVER THE DANUBE RIVER AT CERNAVODA, AUSTRIA. VIEW SHOWING TWO MAIN SPANS COMPLETED AND THE PIERS SUPPORTING THEM UNDER CONSTRUCTION.

The contract for the construction of the Cernavoda bridge, not including approaches, was awarded to the Societe de Fives-Lille, of France, for $1,570,000. This estimate was based on a rate for the superstructure of $135.40 per ton weight, including erecting and painting. The estimated weight was 5,150 tons; the actual is about 5,500. The construction of the river piers was attended with unusual difficulties. It was required that they be built on bed-rock, and to accomplish this it was necessary to sink the caissons to a depth of 101 ft. below water level. Much difficulty was experienced in working at this great depth, the extreme pressure proving fatal to a number of laborers. The total height of the pier is 207 ft., giving the floor of the bridge an elevation of 121 ft. above high water level. The dimensions of the various portions of the piers and the materials used in their construction are indicated in Fig. 3.

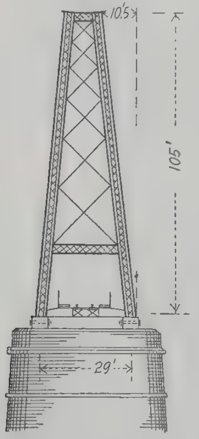


Fig. 2.—End Elevation of Pier, showing Inclination of Trusses.

There are four river piers, each two supporting a span 790 ft. long, consisting of two end cantilevers, each 164 ft. in length, and a central truss construction. The spaces remaining are filled with three 295-ft. truss spans, having half parabolic top chords. An elevation of the bridge, showing length of various parts, is given in Fig. 1. The width of the bridge at the floor level varies from 29 ft. at the piers to 21 ft. at the ends of the cantilevers. These widths are maintained throughout the 467 ft. and the 295 ft. portions. Fig. 2 is the end elevation of the superstructure at a pier. One of the most noticeable features of the construction, the rapid narrowing from bottom to top chords, is here shown. The slope of the trusses is 1 : 10 with the vertical. Basic open hearth steel of a tensile strength of from 59,000 to 68,000 lbs. per sq. in. is used on the main bridge. The elongation at failure in tests of this steel was about 20%, and the elastic limit was about 34,000 lbs. per sq. in. On the approaches a milder grade of steel was used.

The two main spans of the superstructure, as shown in the photograph of the bridge, were erected at the same time with the piers themselves. They were first lifted by trestles to high water level. From that point they were raised by hydraulic jacks on the piers. The jacks were supported on pipes imbedded in the masonry of the piers, there being four pipes in each pier, used in pairs. While one pair was being extended, the other supported the weight on the jacks. In this way ample space for working at the top of the piers was obtained. Fig. 4 shows the floor construction, with the method of imbedding the ties in cement, the whole being underlaid with iron. The bridge is crossed by but a single track.

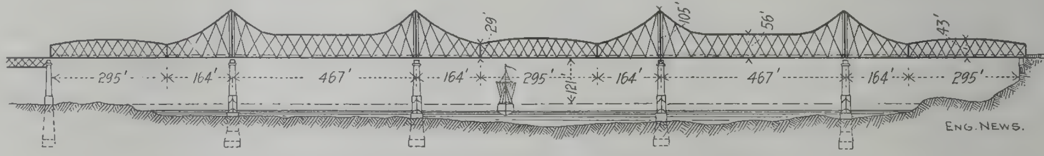

Fig. 1.—ELEVATION OF THE CERNAVODA BRIDGE.

The approaches and viaduct present no features of particular interest, except, perhaps, the solidity and permanency of construction prevailing throughout. The masonry piers are surmounted by trusses of ordinary type. The embankment is built in a substantial manner, with a generous use of rip-rap. The Borcea bridge is similar in appearance to the larger structure. It has but two river piers, which support a 790-ft. span like the central spans of the Cernavoda bridge, and connection to shore is made by two 295-ft. half parabolic spans, as before. The bridge floor is 62 ft. above high water level.

The total cost of the work, including both bridges and all approaches, was, in round numbers, $6,000,000.

STANDARD SPECIFICATIONS FOR STEEL; ASSOCIATION OF AMERICAN STEEL MANUFACTURERS.

The Association of American Steel Manufacturers has recently revised its standard specifications, and we are indebted to Mr. H. H. Campbell, Secretary of the Association, for an official copy of the specifications as now adopted. After the adoption of certain changes it was deemed advisable to reword the entire matter, the revised specifications being then submitted to three members of the association, and after their criticisms the corrected specifications were sent to all the members. We print below the final form of the specifications in full; and this form has been approved by quite a number of the members and will, without doubt, be the final one. As will be noted by comparing these with the specifications first adopted, the consideration of the chemical, as well as the physical properties of structural steel in the later specifications constitute the chief points of difference and a marked step in advance, as pointed out in a letter from a correspondent in another column.

Standard Specifications Governing the Chemical and Physical Properties of Structural and Special Open Hearth Plate and Rivet Steel as Adopted by the Association of American Steel Manufacturers on Aug. 9, 1895; Revised July 17, 1896.

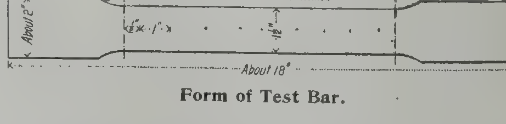
Structural Steel.

Process of Manufacture.—(1). Steel may be made by either the Open Hearth or Bessemer process.

Test Pieces.—(2). All tests and inspections shall be made at places of manufacture prior to shipment.

(3). The tensile strength, limit of elasticity and ductility shall be determined from a standard test piece cut from the finished material. The standard shape of the test piece for sheared plates shall be as shown by the following sketch:

On tests cut from other material, the test piece may be either the same as for plates or it may be planed or turned parallel throughout its entire length. The elongation shall be measured on an original length of 8 ins., except when the thickness of the finished material is 5-16-in. or less, in which case the elongation shall be measured in a length equal to sixteen times the thickness; and except in rounds of ⅝-in. or less in diameter, in which case the elongation shall be measured in a length equal to eight times the diameter of section tested. Two test pieces shall be taken from each melt or blow of finished material, one for tension and one for bending.



Form of Test Bar.

(3a). Material which is to be used without annealing or

further treatment is to be tested in the condition in which it comes from the rolls. When material is to be annealed or otherwise treated before use, the specimen representing such material is to be similarly treated before tested.

(4). Every finished piece of steel shall be stamped with the blow or melt number, and steel for pins shall have the blow or melt numbers stamped on the ends. Rivet and lacing steel, and small pieces for pin plates and stiffeners, may be shipped in bundles securely wired together with a blow or melt number on a metal tag attached.

Finish.—(5). Finished bars must be free from injurious seams, flaws or cracks, and have a workmanlike finish.

Chemical Properties.—(6). Steel for buildings, train sheds, highway bridges and similar structures shall not contain more than 10% of phosphorus.

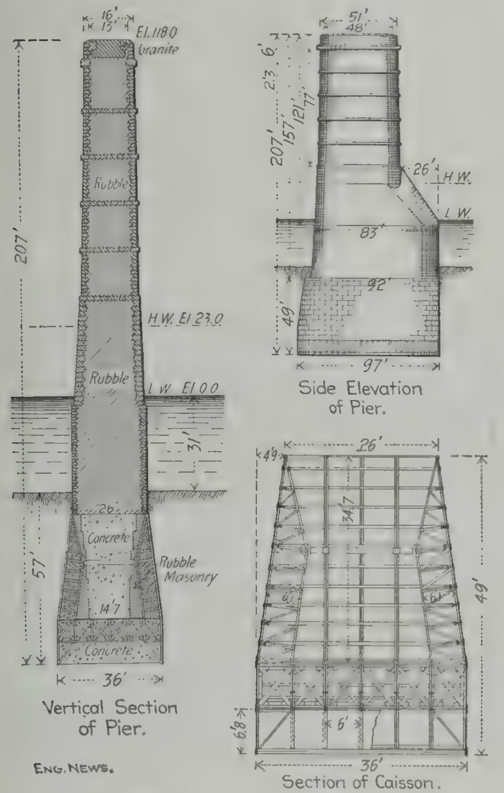

Fig. 3.—Elevation and Sectional Views of Pier and Caisson.

(7). Steel for railway bridges shall not contain more than .08% of phosphorus.

Physical Properties.—(8). Structural steel shall be of three grades: rivet, soft and medium.

Rivet Steel.—(9). Ultimate strength, 48,000 to 58,000 lbs. per sq. in. Elastic limit, not less than one-half the ultimate strength. Elongation, 26%. Bending test, 180° flat on itself, without fracture on outside of bent portion.

Soft Steel.—(10). Ultimate strength, 52,000 to 62,000 lbs. per sq. in. Elastic limit, not less than one-half the ultimate strength. Elongation, 25%. Bending test, 180° flat on itself, without fracture on outside of bent portion.

Medium Steel.—(11). Ultimate strength, 60,000 to 70,000 lbs. per sq. in. Elastic limit, not less than one-half the ultimate strength. Elongation, 22%. Bending test, 180° to a diameter equal to thickness of piece tested, without fracture on outside of bent portion.

Pin Steel.—(12). Pins made from either of the above-mentioned grades of steel shall, on specimen test pieces cut at a depth of 1 in. from surface of finished material, fill the physical requirements of the grade of steel from which they are rolled, for ultimate strength, elastic limit and bending, but the required elongation shall be decreased 5%.

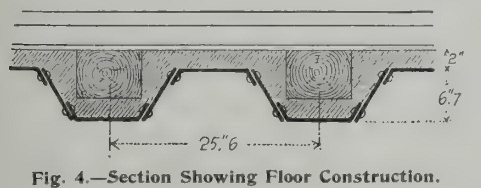

Fig. 4.—Section Showing Floor Construction.

Eye-Bar Steel.—(13). Eye-bar material, 1½ ins. and less in thickness, made of either of the above-mentioned grades of steel, shall, on test pieces cut from finished material, fill the requirements of the grade of steel from which it is rolled. For thicknesses greater than 1½ ins. there will be allowed a reduction in percentage of elongation of 1% for each ⅛-in. increase of thickness, to a minimum of 20% for medium steel and 22% for soft steel.

Full Size Test of Steel Eye-Bars.—(14). Full size test of steel eye-bars shall be required to show not less than 10% elongation in the body of the bar, and tensile strength not more than 5,000 lbs. below the minimum tensile strength required in specimen tests of the grade of steel from which they are rolled. The bars will be required to break in the body, but should a bar break in the head, but devolop 10% elongation and the ultimate strength specified, it shall not be cause for rejection, provided not more than one-third of the total number of bars tested break in the head; otherwise the entire lot will be rejected.

Variation in Weight.—(15). The variation in cross-section or weight of more than 2½% from that specified will be sufficient cause for rejection, except in the case of sheared plates, which will be covered by the following permissible variations, provided that no plate shall be rejected for light gage measuring 1-100-in. or less below the ordered thickness.

(15a). Plates 12½ lbs. per sq. ft. or heavier when ordered to weight shall not average more than 2½% variation above or 2½% below the theoretical weight.

(15b). Plates from 10 to 12½ lbs. per sq. ft. when ordered to weight shall not average a greater variation than the following: Up to 75 ins. wide, 2½% above, or 2½% below the theoretical weight; 75 ins. and over, 5% above or 5% below the theoretical weight.

(15c). Rectangular plates, ¼-in. thick and heavier, when ordered to gage, shall not average a greater variation than the following:

Table of Allowances for Overweight for Rectangular Plates.

(Note.—The weight of 1 cu. in. of rolled steel is taken at 0.2833 lbs.)

Plate	Width of plate		
	Up to 75 ins.	75 to 100 ins.	Over 100 ins.
¼-in. thickness	10 %	14 %	18 %
5-16-in. "	8 %	12 %	16 %
⅜-in. "	7 %	10 %	13 %
7-16-in. "	6 %	8 %	10 %
½-in. "	5 %	7 %	9 %
9-16-in. "	4½ %	6½ %	8½ %
⅝-in. "	4 %	6 %	8 %
Over ⅝-in. thickness..	3½ %	5 %	6½ %

(15d). Rectangular plates under ¼-in. in thickness when ordered to gage shall not average a greater variation than the following:

Thickness of plate.	Width of plate	
	Up to 50 ins.	50-in. and abv.
⅛-in. up to 5-32-in.	10 %	15
5-32-in. up to 3-16-in.........	8½	12½
3-16-in. up to ¼-in	7	10

Structural Cast Iron.

(1). Except when chilled iron is specified, all castings shall be tough gray iron, free from injurious cold-shuts or blow-holes true to pattern, and of a workmanlike finish. Sample pieces 1 in. square, cast from the same heat of metal in sand molds, shall be capable of sustaining, on a clear span of 4 ft. 8 ins., a central load of 500 lbs. when tested in the rough bar.

Special Open Hearth and Rivet Steel.

Test Pieces.—(1). All tests and inspections shall be made at place of manufacture prior to shipment.

(2). The tensile strength, limit of elasticity and ductility, shall be determined from a standard test piece cut from the finished material. The standard shape of the test piece for sheared plates shall be as shown by the sketch.

On tests cut from other material the test piece may be either the same as for plates, or it may be planed or turned parallel throughout its entire length. The elongation shall be measured on an original length of 8 ins., except when the thickness of the finished material is 5-16-in. or less, in which case the elongation shall be measured in a length equal to sixteen times the thickness; and except in rounds of ⅝-in. or less in diameter, in which case the elongation shall be measured in a length equal to eight times the diameter of section tested. Four test pieces shall be taken from each melt of finished material; two for tension and two for bending.

(3). Material which is to be used without annealing or further treatment is to be tested in the condition in which it comes from the rolls. When material is to be annealed or otherwise treated before use, the specimen representing such material is to be similarly treated before testing.

(4). Every finished piece of steel shall be stamped with the melt number. Rivet steel may be shipped in bundles securely wired together, with the melt number on a metal tag attached.

(5). All plates shall be free from surface defects and have a workmanlike finish.

Chemical Properties.—(6). The maximum allowable limits of phosphorus and sulphur shall be as follows:

(6a). On flange and boiler steels, .06% of phosphorus and .04% of sulphur.

(6b). On fire box and extra soft steels, .04% of phosphorus and .04% of sulphur.

(6c). On boiler rivet steel, .04% of phosphorus and .04% of sulphur.

Physical Properties.—Extra Soft Steel. (7). Ultimate strength, 45,000 to 55,000 lbs. per sq. in. Elastic limit, not less than one-half of the ultimate strength. Elongation, 28%. Cold and quench bends, 180° flat on itself, without fracture on outside of bent portion.

Fire Box Steel. (8). Ultimate strength, 52,000 to 62,000 lbs. per sq. in. Elastic limit not less than one-half the ultimate strength. Elongation, 26%. Cold and quench bends, 180° flat on itself, without fracture on outside of bent portion.

Flange and Boiler Steel. (9). Ultimate strength, 52,000 to 62,000 lbs. per sq. in. Elastic limit, not less than one-half the ultimate strength. Elongation, 25%. Cold and quench bends, 180° flat on itself, without fracture on outside of bent portion.

Boiler Rivet Steel. (10). Steel for boiler rivets shall be made of the extra soft quality specified in paragraph No 7.

Variation in Weight.—The allowances for overweight are to be the same as given in paragraph No. 15, under the head of Structural Steel.

THE WATER-WORKS OF COLORADO SPRINGS AND THE STRICKLER TUNNEL.

(With inset.)

The first water-works system for Colorado Springs, Colo., was completed in 1878, and since that time it has undergone a nearly continuous process of development and improvement until it has now reached a stage which is expected to render any further improvement unnecessary for many years. By the end of 1896 it is expected that the final construction of the plant as planned will be completed. Altogether the work of development has been an arduous one, beset with legal complications and engineering problems of annoying, if not of exceedingly difficult character. As an example of the variety of problems encountered by some of our American cities in securing a water supply, and likewise of the methods adopted to overcome these problems, the work is unusually instructive, but further than this it comprises reservoir, pipe line and tunnel constructions of unusual character. The tunnel work particularly is a task worthy of extended mention, and in the accompanying illustrations and this description, the salient features of the work are given in such detail as their importance seems to warrant. For the information from which this article has been prepared we are indebted to Mr. H. I. Reid, City Engineer, Colorado Springs, Colo., who has planned and carried out the work in all its details. The character of his task and the efficiency with which it has been accomplished is testified by the matter which follows.

The accompanying map, Fig. 1, shows the water-works system of Colorado Springs as planned and constructed. All the various pipe lines, reservoirs and other constructions are shown as far as their general location is concerned.

Original System.

The first system of water-works constructed in 1878 consisted of six miles of 6-in. main, from Ruxton Creek in the town of Manitou to storage reservoir No. 1, and a 12-in. distributing main from the reservoir into town. The reservoir was located 200 ft. above City Hall datum and held 1,250,000 gallons. The main being laid with but a slight covering of earth and the intake, according to reports, being improperly designed, it froze solid the first winter. To correct the error a new main of 10 ins. and 8 ins. diameter was laid in 1880. Altogether this experiment cost the city $40,000.

New System.

In 1884, Mr. H. I. Reid was employed by the city to investigate the different sources of water supply preparatory to preparing a general plan for future operations. Careful study of all details regarding supply, drainage area, precipitation, freedom from pollution, and comparative cost led to but one conclusion, and this was that the Pike's Peak region was the proper source of supply. The city which was to be supplied, Colorado Springs, is a health and tourists' resort, and consequently few restrictions are placed upon the use of water. Lawn sprinkling is permitted free of charge and no meters are used. Naturally the citizens were not slow to take advantage of this freedom, and the consumption of water exceeds 300 gallons per capita per day. In view of these facts it was assumed that it was desirable to plan the system for a population of 25,000 people using 200 gallons per day each, and this was done.

Storage Reservoir No. 2.—The first work done was to build a second storage reservoir about 400 ft. from the reservoir of the old system. This site was the Mesa, having a slope of 4% to the south and was the only one available for a reservoir unless a new supply main was to be constructed, which was not at once possible. At the location selected the reservoir could be supplied by a bypass around reservoir No. 1 from the original 8-in. pipe. Besides this by-pass a new pipe was laid connecting the two reservoirs at high water line, and a 16-in. distributing main was carried into the city. Briefly described the new reservoir has a capacity of 14,500,000 gallons and being excavated in the side hill has embankments on three sides only. The cross-section of these embankments is 20 ft. wide on top, with an inside slope of 3 to 1 and an outside slope of 2½ to 1. All pipes through the embankment are incased in concrete masonry and have projecting collars at each joint. In regard to the construction of this reservoir the engineer, Mr. H. I. Reid, writes:

> In constructing these embankments the writer learned from actual experience two important facts, relating to safe construction: (1) A large percentage of clay is not desirable, and (2) too great a quantity of water used in wetting the embankment is worse than no water. More especially is this true if a large amount of clay is used.

New Supply Mains.—As stated above, the new storage reservoir No. 2 took its water from the old 8-in. supply main. This provided for temporary demands, but it was necessary to construct an additional supply main to provide for the assumed demand of 5,000,000 gallons per day. Making due allowances for the original pipe it was found that a 16-in. supply main was needed, and after some opposition, on account of cost, its construction was begun in February, 1889, and completed in December of the same year. During this period several months' delay were caused by litigation for right of way through a neighboring town. Heavy cast-iron pipe was used and considerable time was spent to secure the best possible location and alinement. The pipe was laid on regular curve and tangent alinement, and all depressions and summits avoided. Where possible, without too great deflection, the line follows the streets and highways. The general profile of the pipe line is as follows: Elevation of intake, 6,619 ft.; elevation of reservoir, 6,226 ft.; elevation of City Hall, 6,026 ft.; length of line, 6.73 miles.

This 16-in. main does not enter the new storage reservoir, but connects with the 16-in. distributing main running from it as before described. Thus the new reservoir acts as a stand-pipe for the new supply main. When there is a heavy draft, water is drawn both from the supply main and the reservoir; but otherwise the water backs up from the main into the reservoir. Provisions are made for cutting off the reservoir supply so that if desired—in case of a large fire, for example—the water may be taken direct from the main with a pressure due to a head of 593 ft. Such use has never yet been made, however, and will not be until a pressure regulator has been placed so that the pressure cannot exceed 150 lbs. per sq. in.

All the work on the pipe line, and, indeed, all other work, except where especially mentioned, was done by day labor, and regarding it City Engineer Reid writes:

> The practical observations of the writer upon this work are that much time given to careful alinement and to minute details of construction is amply rewarded in the increased supply of water and the small cost of maintenance. This was practically demonstrated. We had parallel mains with the same intake point. Points were selected where the length and head were the same for both mains and the discharge of each was measured by a current meter. Making due allowance for the greater length of time the old pipe had been used, although this pipe is apparently as free from incrustation now as when laid, it was found that the old pipe had a measured capacity less than the calculated capacity for rough pipe, while the new pipe had a measured capacity somewhat greater than the calculated capacity for smooth pipe.

Bear and Cheyenne Creek Supplies.—As soon as the construction of the Ruxton Creek supply main was completed, work was begun on an additional main from Bear Creek, it having been previously determined that the water from this stream could be injected into the system by a pipe line 2½ miles long, and further, that at a point some eight miles up the stream Cheyenne Creek could be diverted, carried through a low pass, and emptied into Bear Creek, thus saving the cost of eight miles of pipe which would have been necessary had Cheyenne Creek been tapped at a lower point near the mouth of the canyon. A point was selected for intake purposes on Bear Creek at the same elevation as the Ruxton Creek intake. From this point a 12-in. main was constructed to the city. Some four miles above the intake the waters of Cheyenne Creek were let into Bear Creek by a ditch between the two streams. Subsequently, sewer pipe was laid in this ditch and it greatly diminished the loss of water. This work being completed, attention was turned toward constructing storage reservoirs in the Pike's Peak region. The first work was the Lake Moraine reservoir, which is described in the following excerpt from notes sent us by City Engineer Reid:

> Lake Moraine Reservoir.—This reservoir is located near the head waters of Ruxton Creek, about eleven miles west of Colorado Springs and at an elevation of 10,246.8 ft. Its capacity is 492,000,000 gallons and the total area covered is 96 acres, wholly within the original boundaries of the Pike's Peak Military Reservation. In speaking of this basin the eminent geologist, Prof. Arthur Lakes wrote: "At one time the whole valley was occupied first by a glacier and later by a lake over a mile in length, dammed back by a wide moraine thrown right across the valley; but at some time this principal moraine was broken through and the waters of the lake were discharged down a steep narrow ravine along the path of what is called Ruxton Creek, leaving only the small circular lake behind it."
>
> This little lake, 24 ft. deep and covering an area of about 15 acres, was formerly known as "Mystic Lake," probably from the fact that it has no visible inlet nor outlet yet is always full of pure and clear water. Later, however, it was called Lake Moraine. On the opposite side of the valley there is a basin which is almost the exact duplicate of Lake Moraine in form and capacity, yet holding no water until submerged, although its lowest point is lower than its counterpart and many feet below Ruxton Creek which flows between. The cross section profile, Fig. 2, illustrates this better than words can express. To construct the reservoir what we did was simply to repair the breach which caused the drainage of the ancient lake and to utilize the spill-way which nature had so kindly prepared and used in ages gone by. This spill-way is indeed a suggestion, which the engineer is wise in copying where possible. It is located 700 ft. distant from the dam. The water flows off from the side of the reservoir and, making a wide detour, comes back into the main stream one-half mile below the dam. Between the dam and spill-way is a morainal deposit 30 ft. higher than the dam.
>
> The dam, Fig. 3, is 422 ft. long on top; 150 ft. long on the bottom, and has a top width of 20 ft. The inner slope is 3 to 1 and the outer slope 2 to 1. Both slopes are covered to a depth of 2 ft. from toe to crest with broken granite. The crest of the dam is 8 ft. above high water level and the greatest height of the dam is 35 ft.
>
> The materials used were good for the purpose intended, being composed of coarse gravel, fine gravel, sand, and clay in about the proportions 4, 3, 1, and 2, respectively. The entire base of the dam was stripped to a depth below frost line and the puddle trenches carried down to a depth of 14 ft. below the surface or 4 ft. into the clay. Test pits dug 11 ft. deeper failed to define the depth of the clay stratum. It required a great deal of blasting to clear the borrow pits of granite boulders left by glacier drift, but these were utilized in slope paving and for the valve chamber, although for this latter use they were very poorly adapted. In fact we had to select such stone as somewhat resembled a cubical form, as dressing was out of the question.
>
> The valve chamber, Fig. 4, here, as in all of our mountain dams, is placed back free from the action of ice, but always in excavation in the natural earth at the end of the dam. In this case the outlet pipe parallels the inner toe of the slope to the valve chamber, on the high water line, thence turns nearly at right angles to center line of dam and passes to the outer toe. The pipe from chamber to inlet is under pressure, but we find this preferable to having the chamber in the water. The pipe thoughout is encased in concrete and a collar is placed at 12-ft. intervals. The winter weather at this altitude is severe, and from June 1 to Nov. 1 was the only time at which work could be carried on during the year. At the time construction was commenced there was no road nearer than four miles from the site, and all materials had to be carried in on burros over the old United States Pike's Peak trail. This was laborious and costly, and we immediately began constructing a road to connect with the Seven Lakes toll road four miles distant and in an opposite direction to Colorado Springs. This gave us a wagon road inlet, but the road mentioned is very steep and the length about 24 miles, or twice the distance to town over a direct line. There is now a wagon road completed direct down Bear Creek Canyon, also a road connecting with the Pike's Peak rack railway at Mountain View station.
>
> Proposals for this work were received and rejected because excessive; received a second time and again rejected for the same cause, and finally it was let by contract to furnish tools and all labor at so much per day. Mr. David McShaw, of this city, was the contractor. The lowest bid received for this work by yardage amounted to $28,000, and the cost of the work as carried out was $22,000. Mr. Delos Durfee, one of the present assistants in this office, was resident engineer in charge of the work.
>
> Provision was made for wetting the dam, but nature is very lavish with her down-pour of rain at this altitude during the summer months, so that it was a more difficult matter to keep the work sufficiently dry and not lose too much time.
>
> The dam is built up in parallel layers, 4 to 6 ins. thick, but the middle third was kept about 2 ft. higher than the outer thirds, which slope gently from the center in order to quickly shed the rain fall. We find it a wise precaution in all dams and absolutely necessary in the Mountain System, to lower the water 4 to 6 ft. below high water line every fall before the reservoir is frozen over. If this is not done the ice displaces the riprap and leaves the dam in a loosened condition for wave action at high water line, all of which is avoided by lowering in early fall and quickly covering the ice line by water in spring time.

Beaver Creek Pipe Line.—It was known that the waters from Middle Beaver Creek, on the west side of the ridge, could be diverted across Seven Lakes Divide and emptied into Ruxton Creek above Lake Moraine reservoir; also, that West Beaver Creek could be turned into Middle Beaver Creek above such a conduit either by means of a flume or a tunnel, and further, that the best available location for storage reservoirs was to be found on these streams. It was therefore deemed advisable to obtain water rights on Beaver Creek and to this end prices were obtained on several ranches having the oldest and best water rights of this stream. These ranches were located near the confluence of Beaver Creek with the Arkansas River, some 40 miles below the point where it was desired to divert the former stream. Two questions now arose: (1) Having purchased a water right on lower Beaver Creek, could the point of diverting this water be transferred 40 miles up the stream?, and (2), should this be legal, could this diverted water be turned into another stream having an entirely different watershed? To decide these questions a friendly suit was instituted between the city of Colorado Springs and Mr. Wm. Strickler and carried to the Supreme Court, where it was decided that the point of diversion could be changed without effecting priority. In the second case the state legislature enacted a law permitting the diversion from one watershed into a different one and also enacted the above court decision into a law. These questions being settled, the city purchased two ranches for $28,000, the combined capacities of whose water rights were 17.12 cu. ft. per sec.

Immediately work was begun on the necessary conduit from Beaver Creek to Ruxton Creek. The conditions were as follows: About 1¾ miles southwest of Lake Moraine dam is the lowest pass in the range known as Seven Lakes Divide. The elevation here is 11,070 ft., or 812 ft. higher than Lake Moraine. Less than one mile distant, and 120 ft. lower than this divide is the valley of Middle Beaver Creek. By constructing a pipe line 8,400 ft. long sufficient elevation is gained to carry the waters of this creek and its tributaries to Seven Lakes Divide whence it flows down the mountain side into Lake Moraine reservoir. A year previous to this construction a ditch was built for the same purpose and is still used to some extent in the summer time. This pipe is steel, 16 ins. in diameter and light weight in order to avoid excess weight in hauling to the works. Its capacity is 7½ cu. ft. per sec. and it carries the full capacity of the stream except during the two summer months when the ditch is also used if needed. This work was contracted but before half completed the contractor "threw up the job" and the work was completed by force account. It is proper to state here that while the greater portion of these water-works has been constructed by day labor, it was because the engineers were never able to secure a reasonable bid for any mountain work until the past year. The altitude, climate and difficulty in conveying materials, together with the uncertain character of the work, all made the bids excessive, as was afterwards proven by day labor construction.

Ruxton Creek Extension.—Hardly had the Beaver Creek pipe line been completed when a new problem arose. The Manitou & Pike's Peak Ry. is constructed very nearly along the water grade of Ruxton Creek, and this water formerly so clear and pure was rendered more or less muddy from grade washings and from the tourist travel and campers. The stream, it was thought, polluted the water to too great an extent for drinking purposes of a health resort, and it was deemed advisable to extend the supply main up stream a distance of three miles, where the road leaves the canyon. Previous to this time, however, Congress had given the city 700 acres of land surrounding Lake Moraine, so the city now purchased from private parties all the lands on either side of the canyon from the Lake Moraine grant to the rock road, thereby saving cost of constructing 2½ miles of pipe to reach the lake and also receiving the flow from the numerous branches and springs below the lake.

This construction was expensive, as is plainly indicated by the views, Figs. 5 and 6. A heavy wrought iron pipe with Mathewson joints was used, anticipating the early use of this water for power purposes, as well as domestic uses. This pipe line has a total fall of 2,428.8 ft. without a break, but has no dips or summits. The center line is parallel with and 8 ft. from the center of the railway, except at one point where it diverges for a distance of 700 ft. to avoid heavy blasting in the granite cut through which the road posses. On this diverging line huge masses of granite boulders were encountered and at two points the line passed under them by tunnels.

All material for this work was hauled by the rack-road, and the city was not allowed to begin construction, could not in fact, until the road had ceased operations for the summer. The contract with the company owning the road compelled the city to fully protect the track at all times, and, as a precautionary measure, the pipe was laid between the track and the creek, which made it necessary to cross under the rack-road at three points. The weather was very cold, but this proved to be a great help and saving in cost of construction, where the road was on embankment. At such places the pipe line came on embankment slopes, which were about 1 to 1, and were composed of disintegrated granite or gravel. To excavate a bench on this slope of sufficient width for the pipe and at the same time preserve intact the track, was no easy work. In some places sheet piling was driven by hand to support the track side, a bench shoveled off, the pipe laid and the original surface restored with materials borrowed from the opposite side of the track. Generally, however, the track side of the trench was sprinkled with water from the creek near by and in freezing it supported the track in perfect shape.

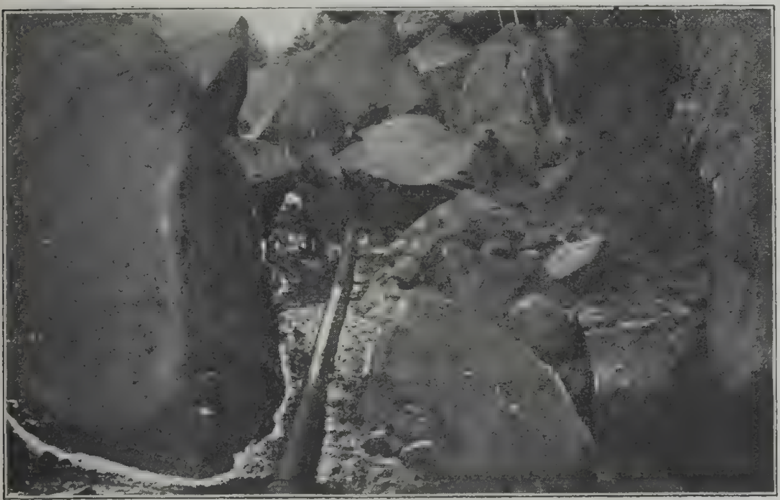

FIG. 5.—VIEW ON RUXTON CREEK PIPE LINE SHOWING TUNNEL UNDER BOULDERS.

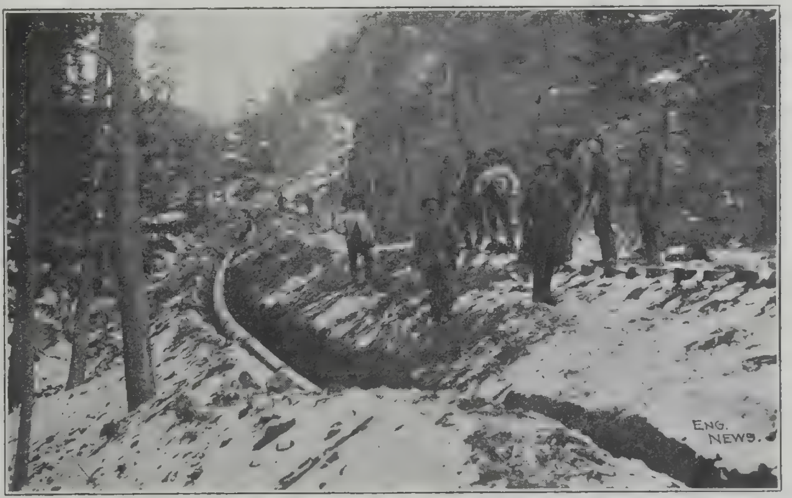

FIG. 6.—VIEW ON RUXTON CREEK PIPE LINE SHOWING CURVE AT HALF-WAY HOUSE.

A considerable portion of the roadbed was in excavation and here the pipe trenching was in solid granite and to excavate a trench at the end of the ties, of sufficient depth and preserve the track, was a more difficult task than the embankment work. This was done, though, and the crossings under the track blasted out without unbolting the rail joints, but it was tedious and costly.

At frequent intervals along the line and at all points where the pipe was on embankment and on the outer side of the curve of roadway, anchors were placed. These were made of steel, a draw band with two bolts around the pipe and a steel rod; one end having a forged eye to receive the bolt of draw band. the other turned at a right angle and placed in hole drilled in the granite walls where most convenient, and the remaining cavity filled with lead. The city blacksmiths made all these anchors and they were found to be cheap, simple and efficient.

Reservoir No. 2 (Beaver Creek system).—The next step was to complete the storage system of which reservoir No. 2 was the first work. It is located on Middle Beaver Creek one mile above the intake of the Beaver Creek pipe line already mentioned. The dam is 725 ft. long; maximum fill 30 ft., with top width and slopes of the standard dimensions previously given. The construction, however, differs from the other dams alluded to in some respects. Earth was a very scarce article, while granite boulders were plentiful, so the outer third was constructed entirely of granite boulders laid in by hand and faced with such earthy materials as were available.

Timber Line Flume.—To divert the waters of West Beaver Creek into Middle Beaver Creek it was necessary to resort to one of three methods: (1) A flume seven miles long; (2) a tunnel 6,400 ft. long, or (3) a pumping plant. For this last method the head in the pipe line could be utilized for generating electricity as a motor power. The tunnel was finally adopted, but for temporary supply a branch of West Beaver Creek was diverted by means of a flume 4,000 ft. long and carried over the divide through which the tunnel is now being driven, At that time it was not expected that the tunnel would be constructed for several years, but being suddenly confronted with a formidable rival in Cripple Creek, Victor and several other towns of this mining district which have a combined population of 30,000 people and are rapidly increasing in size, and further, the only practicable source from which they may receive a water supply being this same Beaver Creek, it was thought wise and proper to push forward as rapidly as possible the construction of Strickler Tunnel. The lumber used in this flume is Southern pine and the cost of transportation from Colorado Springs to the location (17 miles) exceeded the price paid for the lumber plus the freight from Texas.

Strickler Tunnel.—From the foregoing it will be seen that the construction of the Strickler Tunnel is simply to divert the waters from the western to the eastern slope of Pike's Peak. Fig. 1 shows the location of the tunnel in relation to other parts of the system. The total length of excavation is 6,427 ft., of which about 150 ft. at west end and 35 ft. at east end will be open cuts, leaving a net tunnel length between portals of 6,242 ft. The west portal and intake is located at the confluence of two branches of West Beaver Creek and the east portal at a point on Middle Beaver Creek, 1,200 ft. from and 500 ft. higher than reservoir No. 2 of the city's system. The grade elevation of the west end of tunnel is 11,540 ft. above sea level, and the gradient used is 0.50 ft. per 100 ft.

The line of the tunnel is a tangent, course N. 88° 40′ E., and passes through the ridge or "hogback" connecting Pike's Peak and Big Horn Mountain. From the west portal, for a distance of 5,300 ft. the surface is a gradual ascent to the top of the ridge, which point is 424 ft. above grade, then dropping rapidly to the east portal which is on the face of a very nearly vertical cliff of red granite coarse and porphyritic. So far as surface indications determine the east 4,200 ft. is through this same formation, but the west 2,000 ft. shows morainal debris, and this portion of the tunnel will probably require timbering. Geologically speaking this ridge is the seat of an ancient glacier which divided at this point. One portion flowed westward and ploughed out the canyon through which West Beaver Creek now flows, another portion flowed southward, forming the valley of Middle Beaver Creek, and ending in a cul de sac near Seven Lakes, two miles below reservoir No. 2. The west portal is 1½ miles west from the summit of Pike's Peak and about four miles east from "Bull Hill" of Cripple Creek fame. The tunnel site is reached via the Manitou & Pike's Peak Ry. to Saddle House Station, from which point a wagon road has been constructed by the city for use in hauling materials for construction of the timber line flume and reservoirs Nos. 7 and 8. The site may also be reached via the Bear Creek Canyon Toll Road, a distance of 20 miles.

In calling for bids it was stated that it was desirable that the cross-section of the tunnel should be the smallest possible for economical construction. Two cross-sections were designed and bids received separately on each. Figs. 7 and 8 show these cross-sections, both in solid rock and where a timber lining is required. Proposals for the work were received from eight different firms, the prices ranging from $7.99 to $21.75 per ft. for tunnel excavation (Eng. News, Jan. 16). The price of Wilson & Jackson, Chicago, Ill., being $12.90 for tunnel excavation, and $4.76 for timbering, and also being for the cross-section 4 ft. × 7 ft. the least price it was adopted. The total cost, as figured from estimated quantities for comparison, is $99,916. The greater number of bids were the same for each cross-section, one firm, however, bid a less price for section Fig. 8 than for section Fig. 7, and this was undoubtedly correct. The cross-section 5 ft. × 6.5 ft. is the more economical one for the contractor. The amounts of excavation per lineal foot for the two sections are 0.94 cu. yd. in solid rock, and 1.9 cu. yd. in timbered excavation for Fig. 7, and 1 cu. yd. and 2.11 cu. yds., respectively, for Fig. 8.

As stated above, when deemed necessary by the engineer the tunnel will be timbered with red or yellow fir or yellow pine, which may be sawed or hewed as most desirable. The inside lines of any timbers must not fall within the prescribed limits of rock section. The sets of timber will be of 8 × 8 ins. or 10 × 10 ins. and placed 3 to 4 ft. apart as the character of materials supported require. Outside of the posts and arch blocks a 4-in. lagging will be placed and the whole set brought to a firm bearing by wedge-shaped keys. Any cavity existing between lagging and sides of tunnel will be filled with stone or timber as contractor may choose.

The foregoing gives the character of the tunnel work sufficiently well. The method of construction was left to the discretion of the contractor with the usual restrictions as to responsibility, safety, etc., and we have secured from the contractors, Wilson & Jackson, of Chicago, Ill., a brief description of their plant and of the system of excavation to be followed. Briefly stated, electricity, generated by water power, will operate an air compressor plant to furnish power for the work.

The Ruxton Creek main, as already noted, extends from Manitou to a point ½ mile above the Half Way House on Pike's Peak. This pipe line has a fall of over 2,400 ft. without dips or summits and a section of the line will be used for power purposes, the primary plant being erected at Minnehaha Station. This plant consists of a 36-in., 220-HP. Pelton wheel which operates a 150-K-W. three-phase generator built by the General Electric Co. From this generator a 3,500 volt current is sent to the east portal of the tunnel, where a step-down transformer supplies a 220-volt current to the motor, which will be described further on. The transmission line consists of three No. 5 wires carried on cross-arm poles, and is provided with lightning arresters at intervals. Altogether the transmission line is nine miles long.

The plant at the east portal of the tunnel consists of a 75-HP. motor, driving a 75-HP. air-compressor, and smaller motors to drive a Sturtevant blower for ventilation, to run the blacksmith shop machinery and to light the tunnel, shop and yards. From the compressor, air will be piped into the tunnel from the east portal and also over the mountain by a 1½-mile 3-in. pipe to the west portal. Two drills will be worked at each end and the air will be also used for derricks and other power machinery.

For taking out the spoil, a trolley carrier system similar to the ones so much used in Chicago packing houses will be employed. A longitudinal timber will be fastened to the tunnel roof directly in the apex of the roof arch, and this timber will carry by means of hangers a steel bar trolley rail on which carriages or trolleys will run. Outside the portal this rail will form a loop so that the carriages can pass around and be taken back to the working face. Each trolley carries a steel pan of 1½ cu. ft. capacity so suspended that by means of a trip it is automatically dumped when it reaches the proper point. At the east end of the tunnel this dump is emptied directly into a deep gorge only a few feet away, and the dump at the west end is almost as favorable.

The contract for the tunnel was awarded Dec. 27, 1895, and shortly thereafter the contractors began erecting the necessary plant, which has only recently been put in operation. Work on the approaches to the tunnel is about completed.

Reservoirs Nos. 7 and 8.—The water from these two reservoirs, which are located on the west slope of the range, will pass through the Strickler tunnel. Both reservoirs are under construction and will be completed this year. The contractors are Ord & Swipe, of Colorado Springs, Colo. Fig. 9 is a cross-section of the dam for reservoir No. 8. This dam is 1,200 ft. long. Owing to scarcity of earth the outer portion of this dam is built of rock, as previously described for reservoir No. 2. Fig. 10 shows the cross-sections of the two dams for reservoir No. 7, which is the highest reservoir of the system, being at an elevation of 12,109 ft. above sea level.

Prospect Lake Reservoir.—There remains to be described only one other reservoir of the domestic supply system of Colorado Springs, viz., the Prospect Lake reservoir, located east of the city. This reservoir was built during the winter of 1890-'91. It is used principally for irrigation and resort purposes, but can be utilized for domestic supply for a considerable portion of the city if necessary. It is located on the opposite side of the town from the Mesa reservoirs already mentioned. The town lies between and on lower ground than either of the reservoirs, Mesa reservoir being 200 ft. and Prospect Lake 80 ft. above City Hall datum. This reservoir basin is a peculiar one. Located on the very summit of a sand mesa, the wind action has gradually ploughed out along the line of prevailing winds, northwest to southeast, a basin 2,800 ft. long, 1,200 ft. wide and 23 ft. maximum depth, leaving natural dams at either end, so that without any work at all it gave a capacity equal to the above dimensions. The engineers simply enlarged this piece of nature's handiwork by increasing the height of the dams, thus submerging the entire basin.

The northwest dam is 1,250 ft. long and 14 ft. deep. The southeast dam is 1,320 ft. long and 12 ft. deep. The slopes in each case are 3 to 1 and 2 to 1 for inner and outer slope, respectively, and the top width is 20 ft. The inner slopes are heavily riprapped with cobblestone. The northwest dam is built up of fine sand and probably 15% of sandy loam, which was moist from melting snow. The southeast dam was composed of fine sand only and was neither moist nor sprinkled. Each dam was constructed by the same parties and in the same manner, but the northwest dam was completed before the other was commenced. The northwest dam seeped considerably the first year, while the dry sand dam has not leaked at all. In order to drain the water from the bottom of this natural basin it was necessary to make an excavation 1,000 ft. long and 23 ft. deep at the greatest cut. A 12-in. supply main from the city system carries the overflow water into this reservoir, which pipe was laid on a slightly ascending grade from a point in the city to the reservoir, so that the pressure from the Mesa reservoir forces the water into Prospect Lake, but when the valve is closed, cutting off Mesa reservoir pressure, then the pressure due to the elevation of Prospect Lake forces the water back through the same main into town for irrigation purposes.

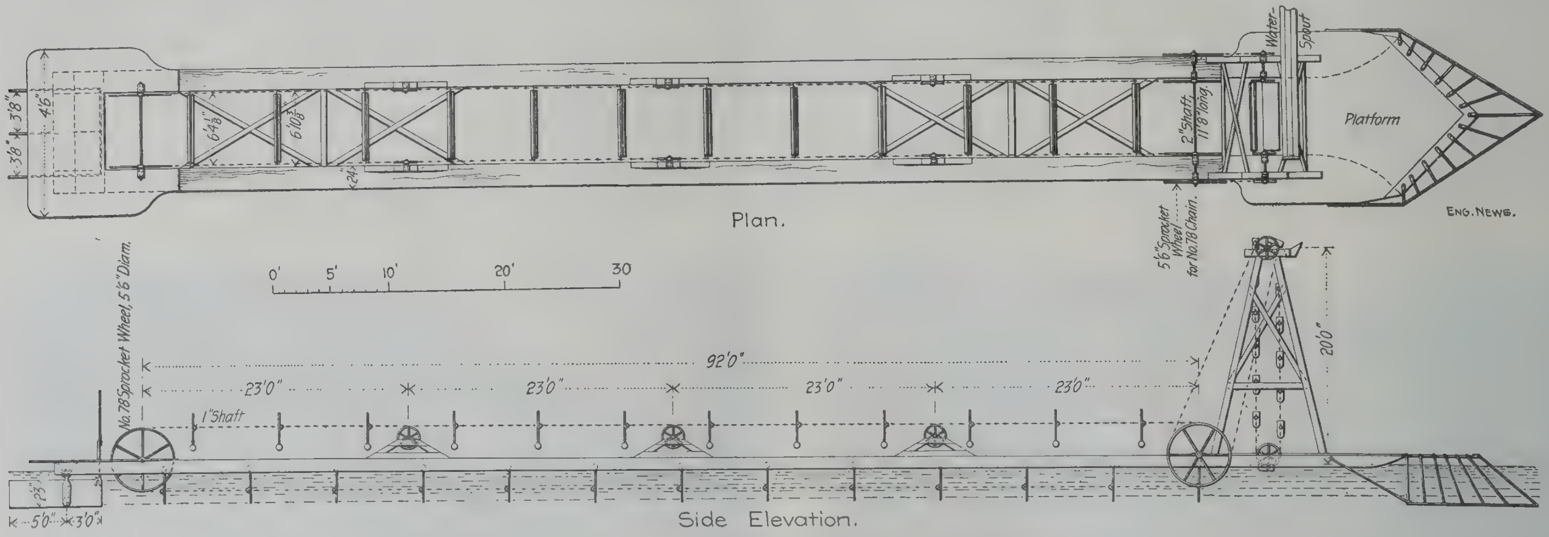
In the foregoing no mention has been made of irrigation reservoirs and pipe lines developed in connection with the domestic water supply system, nor have many of the details shown by the drawings been described. Several minor details to further improve the system will doubtless be developed later and it is quite possible that work may be begun in the near future to develop the water power, which has been made available by the various constructions. At present careful measurements are being made of the rain and snow fall, and all streams are being gaged with the intention of determining very closely just what can be expected in the way of precipitation and runoff of the available watershed.

As stated above the entire work has been designed and carried out by Mr. H. I. Reid, City Engineer, Colorado Springs, Colo. His assistants in all the work have been Messrs. Delos Durfee, E. W. Chase, and E. S. Gandy.

◆

A CURRENT MOTOR FOR PUMPING WATER.

The accompanying illustration shows an interesting machine which has recently been developed specially for the purpose of raising water for irrigating purposes, though it promises to be applicable in a variety of situations. It consists simply of a long narrow float or pontoon, carrying an endless chain to which are attached floats at intervals of about 8 ft., which receive the force of the current. The chain, or rather chains, for there are two which run side by side, carrying the floats between them, run over sprocket wheels at each end of the pontoon, and the wheels at the head transmit the power thus gained to an overhead shaft which lifts the water by an endless chain pump.



PLAN AND ELEVATION OF A CURRENT MOTOR FOR PUMPING WATER.
Designed and Built by the F. C. Austin Mfg. Co., Chicago, Ill.

It will be evident that in a stream with a swift current a very considerable amount of power can be developed by this simple mechanism at very small expense. The system is especially applicable to the streams of the Far West where an unstable bed, or sudden and great floods makes the erection of permanent dams for the development of water-power almost impossible, and where the water often carries silt which would make the operation of almost any type of cylinder pump expensive.

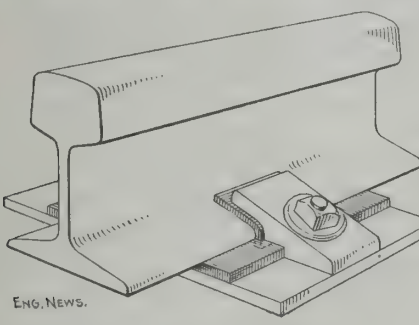
Further, the apparatus is especially adapted to locations where the machinery must be as simple and light as possible on account of difficulties of transportation, and must be susceptible of repair with the crudest of tools. It will be seen that it can be made of any size desired to suit the location in which it is to be placed, the quantity of water desired, the height to which it is to be raised, etc. The apparatus is manufactured by the F. C. Austin Mfg. Co., of Chicago, Ill., a firm which has given special attention to the development of irrigation machinery, and to which we are indebted for the blue-print from which our cut is prepared.

◆

THE SEWALL DYKE FOR LEVEE PROTECTION is being endorsed by the Sugar Planters' Association of Louisiana, and other citizens of that state. The system is that of H. F. and N. H. Sewall, and has been tested for about three years at New Orleans, Bayou Goula and the South Pass. The plan, says the New Orleans "Picayune," is to construct pile spur-dykes, at intervals along a caving bank, projecting up stream "at an angle of about 25°," with the piles driven 30 to 35 ft. into the river bottom. The conditions require piles up to 150 ft. in length and to meet this condition Messrs. Sewall have devised a special form of spliced or continuous pile. At New Orleans the river is 50 ft. deep and the dykes run out about 135 ft., but they have stood the high water of three years. The dyke at Bayou Goula was built in 1894 and terminates in water 115 ft. deep; but has well answered its purpose. The Planters' Association will ask that Congress take this matter in hand directly.

INSULATING RAILS FROM METAL TIES AND BRIDGE FLOORS.

On roads using a track circuit for signal operations and having the rails laid upon metal ties or upon the metal floors of solid floor bridges, it is necessary to provide some efficient means for insulating the rail from its metal supports. We illustrate herewith a method of insulation which is in use on the new Park Ave. viaduct and Harlem River drawbridge of the New York Central R. R., where (as has been described in our columns) the rails are bolted directly to the rectangular transverse troughs which form the floor. The construction was shown in our issue of May 7, 1896, in an article on "Short Span Bridges." There are three pieces of indurated fiber. One forms a bed plate, and has slots for the edges of the two shorter pieces which fit between the rail and the bolted clamps by which the rail is secured to the metal structure or tie. The same device may be applied to wooden ties when desired, substituting two screw spikes for the bolts in the clamps. The patents are owned by the New York Rail Insulation & Equipment Co., 200 Market St., Newark, N. J.



Device for Insulating Rails.

BASIC STEEL RAILS.

The use of basic steel rails having a year or two ago been prohibited on the Austrian State Railways, Prof. Tetmajer, of the Polytechnic School of Zurich, Switzerland, published a paper in which he defended the use of such rails. The action of the Austrian government was due largely to two lots of inferior rails having been furnished by a German company. On the representation of the officers of a large basic Bessemer steel plant the government appointed a commission to investigate the matter (the firm referred to selecting two members), and as a result of this investigation the order was reversed, although basic rails are still required to show a tensile strength of 71,100 lbs. per sq. in., while for ordinary Bessemer rails a tensile strength of only 66,800 lbs. is required.

The defective basic steel rails above referred to were accepted in spite of a low tensile strength, as the rails were needed at once, but after some time defects appeared in the shape of longitudinal splits in the rail heads, sometimes extending nearly the entire length of the rail, a little to one side of the center line, and in some places this split was large and gaping. As the splits did not extend to within a few millimeters of the surface of the head they only became evident after the rails had been worn to some extent. Out of 1,540 tons of these rails furnished and laid in 1890, 122 rails, or nearly 8%, had been removed by the end of 1893. These same defects appeared to a still greater extent in the second lot of rails furnished by the same company, and careful examination showed that the defect existed originally in the steel. The split was not vertical, but followed irregularly the contour of the rail, and its walls showed plain signs of oxidation. In some exceptional cases the ends of the rails were crushed, owing to the softness of the material, but no cross fractures occurred, though such fractures are not uncommon in ordinary Bessemer steel. Defective rails that were tested showed a tensile strength of 62,000 lbs., with 28.3% elongation for the base, and 68,000 lbs., with 24.8% elongation for the web. The specifications required not more than 0.6% manganese and 0.1% each of phosphorus and sulphur, but analyses showed 0.415 to 0.695% manganese and 0,128 to 0,221% phosphorus.

That the rails successfully passed the drop and bending tests is explained by the low percentage of carbon and the absence of silicon, as such rails, even with too much phosphorus, may give good results in these tests and show no transverse fracture. The presence of the longitudinal split following more or less regularly the contour of the section on one side of the rail is due to careless work with the ingots. Blowholes are naturally found disposed symmetrically at a certain distance below the surface of the ingot, and if such an ingot is removed from the mold before the metal has thoroughly set, and is laid on its side on the floor or on a car, the soft interior metal will settle down to the lower side, filling the blowholes on that side, but enlarging those on the upper side, and these latter will form the splits when the ingot is rolled. Unsatisfactory and unreliable results may occur through carelessness in the blowing of the steel, as well as in the casting and handling of the ingots, but Prof. Tetmajer pointed out that it does not follow that the basic Bessemer process should, therefore, be condemned. In well managed works the heats are blown regularly, the phosphorus is brought down below the specified limit and the ingots are not removed until the metal has thoroughly set.

Since 1878 the basic process has developed rapidly. In 1880 only 50,000 tons were made, while in 1893 the output was 3,638,556 metric tons, of which about 20 to 25% was made by the basic open-hearth process. The metal is said to meet with a steadily increasing application in the construction of bridges and railways all over the continent of Europe and in England. As one of the principal objections made to basic steel has been the alleged irregularity of its composition, Prof. Tetmajer gave in his paper a number of analyses showing that great regularity is actually obtained in the output of many large works and referred to the value of the Darby and Meyer recarburization process in this connection, and also states that the basic Bessemer boiler plates of the Peine works compete successfully with the best brands of Siemens-Martin steel.

In Switzerland the principal railways use from 19 to 44% of basic rails, while some secondary railways use basic rails exclusively and others use acid Bessemer rails only. No restrictions are made as to manufacture, but the specifications require that the rails shall be faultless, made from perfectly sound ingots, whose cross sectional area is 20 times that of the rail, and that they must stand cold bending, tensile and chemical tests. Crop ends are usually chosen for the drop and bending tests, while test bars 1 in. diameter are cut from the rail heads for tensile tests. The tensile strength is required by the new Swiss specifications to be 5.5 tons per sq. cm. (about 81,000 lbs. per sq. in.) and the product of this figure and the elongation must be at least 90, which is called the "coefficient of quality." For cold bending a 4-ft. piece of rail is laid on supports 3 ft. 3⅜ ins. apart and must carry for ten minutes without permanent deflection a center load in tons of 0.15 W (W being the moment of resistance of the piece in centimeters), and must also carry a load of 0.25 W without breaking, the permanent deflection in this case being carefully noted. The average chemical composition required is not less than 0.3% carbon, not more than 0.3% silicon, and not more than 0.1% each of phosphorus and sulphur, the proportion of manganese being left to the discretion of the manufacturer. On the Northeastern Railway, of Switzerland, 27,044 basic Bessemer rails were laid between 1885 and 1893, of which 14 were removed (5 for being split, 5 for being crushed, 2 for being broken and 2 for ordinary wear and damage), giving a proportion of 0.518%. Between 1875 and 1893 the same road had laid 134,902 acid Bessemer rails, of which 431 had to be removed (216 broken, 83 split, 54 crushed and 78 worn and damaged), or 0.3195%. It is stated, however, that in the earlier years the rail flanges were notched in some places, which may have increased the percentage of removals of the acid Bessemer rails.

In dealing with the manufacture of basic rails in Germany it was pointed out that the rails from the only two works using the basic Bessemer process show the greatest resistance to wear. Thus the decrease in height of rail per million tons of traffic was 0.005 and 0.018 mm. (or 0.0002 and 0.007-in.) respectively, while the Krupp acid Bessemer rails come third with 0.025 mm. (or 0.00098-in.). This wear is obtained by dividing the decrease in height of the rail by the amount of tonnage in million tons passed over it during the period of observation. Returns from the state railways of Finland and Hungary showed that the wearing quality of basic Bessemer rails is above the general average, in some cases showing a decided superiority. The renewals of defective rails are also less than with acid rails. From the information collected, Prof. Tetmajer concluded that basic Bessemer rail steel can be made with great regularity in its composition and free from oxygen and red shortness, and also that by the application of the Darby and Meyer recarburization processes any grade of hardness can be easily and regularly obtained.

LEGAL DECISIONS OF INTEREST TO ENGINEERS.

When Punitive Damages Will Not be Allowed.

In the absence of evidence, in a personal damage suit against a coal company, of malice or reckless conduct on the part of the company indicating a purpose to have the employee injured, or of a reckless disregard of the safety of the person of the employee the injury should be confined, in case it returns, a verdict against the company, to compensatory damages only.—McHenry Coal Co. v. Sneddon (Ct. App. of Ky.) 34 S. W. Rep., 228.

Assessment Lien, Contract Must Comply with Statute.

A contract reciting that a party would construct curbing and gutter ways in accordance with the specifications thereto annexed, but to which no specifications were annexed, is not a sufficient compliance with a statute requiring all contracts to be in writing and signed by the contractor; and under it no lien can be fixed, against the will of the owner, upon abutting property. A proceeding to charge one with improvements for which he has not contracted must show a strict compliance with the law. —Schwiesau v. Mahon (Supr. Ct. of Cal.) 42 Pac. Rep., 1065.

Railway Bridge and Drainage Construction.

A railroad company's property may be benefited by the drainage afforded its right of way, and at the same time may be damaged by a requirement to remove or alter the construction of its bridge across the proposed drain. If the cost of temporary changes in a railroad bridge to admit of improvements to a stream for drainage purposes do not arise from the railroad company's continuing duty to so maintain its bridge as to admit public rights accruing subsequent to the construction of the bridge, such changes are proper subjects of consideration in the ditch proceedings, and the costs of such changes should be deducted from the assessment of benefits to the company.—Lake Erie & Western Ry. Co. v. Cluggish, drainage comr. (Supr. Ct. of Ind.) 42 N. E. Rep., 743.

Engineer's Estimate, When Not Conclusive.

The provision in a construction contract that, when the work is completed, there shall be a final estimate made by the engineer of the quantity, character and value of the work, agreeably to the terms of the contract, and the balance, after deducting monthly payments, and on the contractor giving a release, will be paid in full, is not an agreement that the engineer's estimate shall be conclusive.—Central Trust Co. v. L., St. L. & T. Ry. Co. (U. S. Cir. Ct. of Ky.) 70 Fed. Rep., 282.

Discretion of Court as to Admission of Engineer's Opinion.

The refusal of the lower court to permit a witness who has testified that he is a professor of civil engineering, and has made the law of moving bodies a study, and can tell how far a train will move by its momentum, to testify as an expert as to the distance such train would travel, in order to contravene the testimony of other witnesses testifying from practical experience, will not be disturbed on appeal.—Blue v. Aberdeen & West End Ry. Co. (Supr. Ct. of N. C.), 23 S. E. Rep., 275.

Liability of Trolley Company for Injuries.

In an action against a street railway company it appeared that in passing a switch at the top of an incline, the trolley had to be adjusted from the rear of the car; that there was but one person in charge of the car, whose position was in front, and that he, without stopping the car, went to the rear end, adjusted the trolley, and got off to run ahead to the front end; and that while running he fell, and was unable to overtake the car, which finally jumped the track and killed a passenger. The Supreme Court of California held that the company was liable. —Redfield v. Oakland Consol. St. Ry. Co., 42 Pac. Rep., 822.

Use of Streets by Gas Company.

A gas company was granted by ordinance the privilege of laying pipes in the streets of a city, subject to the conditions of a prior general ordinance fixing the conditions generally on which corporations could lay pipes, and requiring any such corporation to file with the comptroller a certified copy of a resolution of its board of directors accepting all such conditions. A company filed with such officer a resolution of its directors agreeing to comply with the general ordinance "excepting so far as any of its terms may be held or adjudged illegal or unreasonable by the courts." The court held that the council of said city never having consented to such modification of the acceptance, and the company having enjoyed the privileges of the ordinance under its acceptance, it could not refuse to comply with certain conditions of the ordinance on the ground that after its acceptance they were decided to be illegal.—Allegheny v. Peoples' Nat Gas & Pipage Co. (Supr. Ct. of Penn.) 33 At. Rep., 704.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the* 32d *week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

We illustrate and describe on another page of this issue a structure recently completed which is entitled to rank as one of the great bridges of the world, a cantilever structure over the Danube at Cernavoda, Austria, with a central span of 623 ft. The bridge is of more interest to American engineers, however, by reason of some interesting features in its design. The main trusses at the piers have a total height of 105 ft., and they are inclined toward each other, so that while they are 29 ft. apart at the base they are only 10 ft. 6 ins. apart at the top. Of course previous cantilever bridges have made use of inclined trusses; but it is worth considering whether the idea might not be adopted to advantage in the design of curved chord trusses of every long span.

A still more curious and, so far as we recall an entirely novel feature, is that the width of the cantilevers is greater at the piers than at their ends. The distance between the truss centers at the floor level being 29 ft. at the piers and only 21 ft. at the ends of the cantilevers.

Another notable feature in connection with the Cernavoda bridge is the fact that the main cantilevers were completed before their supporting piers were built, and were raised by hydraulic jacks as the piers were built up. While this may seem an awkward way to carry on work, its advantages in the saving of false-work and risk in erection are evident; and it will be remembered that European engineers have not had the experience in bridge erection over great rivers that we have had in this country, and are presumably willing to go to greater lengths to avoid difficulties in such work.

◆

Our recent comments (in connection with the Atlantic City collision) on the need of installing derailing switches interlocked with the signals at every grade crossing of steam railway lines, have additional force furnished them by a recent accident, unimportant, so far as casualties are concerned, at Danville, Ill. The particulars, as furnished by a correspondent, were as follows: At Danville Junction the Peoria Division of the Cleveland, Cincinnati, Chicago & St. Louis Ry. (better known as the "Big Four") crosses the Wabash R. R. at grade. On Aug. 3 a caboose and four cars of a freight train on the former road were left east of the crossing and ran back down the grade and struck a Wabash freight train which was passing over the crossing, striking about four cars back of the engine. Nine cars were wrecked, but as no trainmen were on them no one was injured. Here is an occurrence which admirably illustrates the fact that a signal system for the protection of a grade crossing cannot be called safe unless some mechanical means of protecting a train using the crossing from trains on the other track is provided. Runaway cars do not obey danger signals, and the much-vaunted appliances for automatically setting the brakes of trains running past a danger signal would have no effect on them. In the case of this Danville accident, it was pure chance that it was not a crowded excursion train which these runaway cars struck instead of a freight train. Had that occurred there would have been a repetition of the Atlantic City horror, and a new demand on the part of the public for the abolition or better protection of grade crossings. Because no one was hurt in this Danville accident the public pays no attention to it, but to a railway officer it should be as instructive as if the dead and injured resulting from it had been numbered by scores.

◆

What may be termed the itinerary investigating committee, especially in connection with the development of public works, is a subject which might be discussed to advantage by students of municipal government and one which directly concerns many engineers and contractors. To come directly to the point with a concrete illustration, a supplementary water supply for the fire protection of Boston, consisting of independent fire mains supplied by powerful engines with water from the harbor, has been under discussion for some years. It is now proposed to have three aldermen and five councilmen, composing the Joint Standing Committee on Fire Department, make a trip to New York, Brooklyn, Philadelphia, Baltimore, Washington, Richmond, Pittsburg, Cincinnati, Cleveland, Buffalo, Detroit, Chicago, Milwaukee and Niagara Falls to study this question, together, it is said, with training schools and veterinary hospitals for fire department horses. It is proposed to invite a representative of the city engineering department to join the expedition. The Boston "Herald," in a brief editorial headed "Eight to One," calls attention to the fact that the investigation will be made by "eight politicians and one expert," as it terms those who are to take part in it, and asks if it might not be well to reverse the numbers.

◆

We know nothing whatever of the character or qualifications of either the "eight" or the "one." We are sure that one capable engineer is all that is needed, ordinarily, for a trip of this sort. Whether eight city fathers are necessary depends altogether upon the point of view from which the matter is considered. Looked at technically, we have no hesitation in saying that one engineer without the other members of the party could learn all that was valuable on the subject in hand, weigh the evidence and recommend a plan best suited to the needs of the city. On the other hand, the practical aspects of city legislation, as now conducted, show that it is one thing to scientifically determine the best mode of procedure and quite another to secure the passage of the necessary legislation. "Seeing is believing," and in the case of the proposed introduction of some public works new to the locality, like brick or asphalt paving, or a garbage disposal plant, the committee having the matter in charge may come back satisfied from an inspection of successful works of the same character in other cities and ready to recommend the adoption of what some or all of them might otherwise think a doubtful experiment, at best, while the confidence of the committee will carry its recommendation through the city council. With good engineering advisers, and proper confidence in them, in many cases where investigating committees have gone out all this would be unnecessary. Often the engineering department possesses all the information needed to decide on the best plan and to carry it out, and where it does not the department could obtain it at much less expense than would be incurred by three or five or a dozen men in their journeyings over the country. As human nature stands, however, it is far easier to secure a large appropriation for such a trip than a small one to conduct engineering investigations. There is much more that might be said on all the various phases of this subject, especially regarding the educative values of these itineraries on the one hand, and on the other hand their superficial character in many cases, their cost, and their occasional dark and devious ways. But it is gratifying to note that there seems to be an increasing tendency to at least take an engineer along, thus profiting by his knowledge and experience as he points out salient features, and sometimes gaining through him for the city valuable information which would otherwise be overlooked.

◆

The decision of Justice Edwards, in the case of the Hilton Bridge Company, New York, vs. the State Superintendent of Public Works, George W. Aldridge, has in it elements of interest to bridge companies and to state officials. The company named applied for a writ of mandamus to compel Mr. Aldridge to award to it the contract for two lift-bridges over the Erie Canal, in Utica. The bridge company claimed that the work was awarded to a lower bidder owing to the fact that certain alterations were made in the successful company's proposal after the bids were opened. This action, the attorney of the bridge company claimed, was illegal and contrary to Section 132, Chapter 338, of the Laws of 1895, which requires that all bids shall be definite and certain, and that no bid which is not definitely certain "shall be received or acted upon." The attorney claims that two items were uncertain in the bid of the successful company and the proposal was only made definite after communicating with this company after the bids were opened. In a short opinion issued, Justice Edwards practically says that the provision of the constitution quoted does not apply to contracts let by the Superintendent of Public Works. He holds that that official is vested with great discretionary powers in awarding contracts and that his action in this matter was perfectly just.

◆

Without knowing more than we do of the actual facts of the case the opinion of Justice Edwards can not be criticised. But it is interesting to know that the State Superintendent of Public Works, of New York, is vested with this unusual power and is not bound by the Constitution of the State. In his hands an award under similar conditions is doubtless safe; but the practice is not a safe one to extend to every official who is to pass judgment upon the character and status of a proposal. To permit any alterations in proposals once unsealed is to at once remove about the only safeguard remaining to the bidder; and while it might sometimes work an injustice to reject all explanation of unintentional blunders in a proposal, that amounts to a change in item prices, this seems to be the only just course to pursue. The law of the state is a wise one and should apply to all alike. The remedy is always left of rejecting all bids and readvertising, thus throwing all bidders back upon a common level.

◆

For the last twenty years the engineers and manufacturers of Europe have been attempting to unite upon uniform methods of testing structural materials with regard to their mechanical properties, and conventions have been already held for this purpose at Munich, Dresden, Berlin and Vienna, attended by representatives of the technical professions. As might be expected in gatherings of this character, opinions differed widely, and while some agreement has been reached, many of the more important problems have yet to be solved, or present solutions revised. Under the existing conditions of trade intercourse any unification of testing methods will have little value unless it be adopted by all manufacturing countries, and hence every effort is, and should be made to secure the views and experience of the greatest number of delegates possible from technical associations and societies. At the last conference delegates attended from Germany, Austria-Hungary, Switzerland, Russia, France, America, Norway, Holland, Italy and Spain, but England was conspicuous by her absence. France, in 1891, created a government commission, having for its object the same as that of the permanent committees appointed at the later conventions, with the added advantage of more readily obtaining the funds needed for experimental research. The promoters of this unification in testing methods rely mainly, however, upon the international character of these conventions and believe that ultimate success can only result from all manufacturing nations uniting upon common standards and methods in the tests of structural materials. To this end they invite the technical representatives of all countries, and that new delegates may better understand the scope of the work proposed and that performed, Prof. J. Bauschinger, of Munich, has published the resolutions passed at the conventions held at Munich, Dresden, Berlin and Vienna, together with a short statement of the reasons for their adoption. This publication has been translated into English by Capt. O. M. Carter, Corps of Engineers, U. S. A., and by E. A. Gieseler, U. S. Assistant Engineer. This translation is issued from the Government Printing Office, at Washington, and can be secured by application. The resolutions referred to cover, in part, the tests of wrought iron and steel, copper, bronze and other metals, tests of wood, stone, paving and ballast materials and hydraulic binding materials. Aside from the great importance of a unification in the methods of tests, the text of this little book is valuable to all engineers as indicating the direction and scope of modern research in this connection.

With a full appreciation of the value of the work proposed at these conventions, it must be admitted that the task set is one difficult of performance, and some time will yet undoubtedly elapse before a thoroughly acceptable and international system of tests of structural materials can be adopted. This end will only come when the best and most experienced engineers of every country can meet in convention, discuss experiences and methods and, aided by special experimental research under standing committees, arrive at a common and intelligent agreement upon the problems presented. The difficulty lies in gathering men of this character together and enlisting them in the common cause. The views of isolated experts have little weight in a crusade of this type; what these conventions aim at is a concensus of the opinions of the technical professions and trades everywhere, and by this means alone can the nations unite upon any common methods of tests. Hence, it is important that every man who has valuable experience in these matters should be represented by communication or in person; and the wider the interest taken in the aims of these conventions the sooner will thoroughly valuable results be given out to all industries and to the technical professions.

AN OPPORTUNITY FOR AN AMERICAN STEEL RAIL PLANT IN AUSTRALIA.

In recent issues we have discussed at some length the prospects for the extension of the export trade of the United States, which is a matter now receiving considerable attention, and bids fair to lead to very considerable changes in our commercial system, but an opening now offered for American business is in a somewhat different line. There is at this present time an opportunity open for some enterprising American capitalists and rail manufacturers to establish themselves in Australia, this opportunity being afforded by the invitation to bid for the contract to manufacture 150,000 tons of steel rails and other track material in the colony of New South Wales, as has been advertised and briefly commented upon in our columns. So far, all the track material for the railways of that colony (which are owned and operated by the colonial government) has been obtained from Europe, and mainly, if not entirely, from England, but the government is desirous of establishing home industries and developing native resources, and for this reason it has taken the initiatory steps toward securing the installation of a complete rail manufacturing plant. In extending this opportunity to American investors and manufacturers the railway authorities have, no doubt, been influenced by the excellent results which have followed the adoption of certain American details of railway practice, and the introduction of American types of locomotives, cars, brakes, etc.

Some considerable time will probably be required for the perfecting of negotiations and financial arrangements among men here who may contemplate entering the competition for the contract, and it will also be necessary to collect a large amount of information upon which to base the preparation of a safe proposal, especially as the bids are to state the prices per ton for rails delivered. The advertisements were first published in July, and the proposals will be received until Dec. 30 by the Secretary for Public Works, at Sydney, and by the Agent-General for New South Wales, in London. There should, therefore, be ample time to make all preliminary arrangements and to send engineers out to make personal investigations as to questions of character, cost and supply of ore, fuel, etc.; available sites, and their distance from the mines and railways; transportation facilities; extent of present iron working industries, cost of machinery, labor conditions, etc. The probability of further contracts for rails, the prospect for undertaking the rolling of structural iron work, etc., and the possibility of securing orders from the other Australian colonies, are also points to be considered.

The contract stipulates that the rails and other materials are to be manufactured in the colony, using native iron ore and other necessary minerals, and native coal, coke or other fuel, all raised and smelted in the colony. The delivery of rails is to commence within 18 months after the contract is signed, and is to be at the rate of 15,000 tons per annum for ten years, reckoned from the date of the first delivery. The other materials are to be delivered in quantities corresponding with the requirements of the track for which the rails are supplied. The total amount of material contracted for will be as follows: Steel rails, 150,000 tons; steel splice bars, 7 per cent. of the total weight of rails supplied (10,500 tons); steel track bolts, 7 per cent. of the total weight of rails supplied (10,500 tons); steel spikes, 6,000 tons.

The bids submitted must state the prices per ton for rails and other material delivered at the railway station most convenient to the works, and must be accompanied by a deposit of £5,000 ($25,000), the deposit of the successful bidder being retained by the government until the works have been completed and the delivery of rails commenced, and being forfeited if the bidder does not execute the contract within 30 days of his bid being accepted by the Minister of Public Works. All the work is to be done under the supervision of the Engineer-in-Chief for Railway Construction, and in accordance with drawings and specifications prepared by him, which accompany the contract, but are subject to change as to dimensions and weights required. The men are to be paid their wages at least once a month in current coin of the colony, the truck system or any other such system of payment by tickets for provisions, etc., being strictly forbidden. It is also provided that in the event of any failure on the part of the contractor to pay the claims of any tradesmen, workmen or laborers in full in current coin of the colony, the Minister of Public Works or the Engineer may pay the amount of the claim and deduct the same from any money due or becoming due to the contractor. The labor element has become very prominent and powerful in the colony, and it will be seen that ample care has been taken by the government to protect the men employed in the proposed rail works. The contract must not be assigned or sublet by the successful bidder. Progress payments may be made to the contractor monthly, in the proportion of 85 per cent. of the value of the material turned out.

In the early days of the New South Wales Government Railways, the English type of track was largely used, with 75-lb. double-head rails supported in heavy cast-iron chairs. The American type of track, however, with T-rails laid directly upon the ties, has been found far more satisfactory, and the contract above noted includes only T-rails of 60 and 80-lbs. per yd., but it is stated that the length is to be 30 or 40 ft., as required. The designs of the rails and angle bars show the influence of American practice, but the rail heads are open to criticism in the roundness of the tops (10-ins. top radius and ⅜-in. corner radius), while the splice bars are thick in the web but have a very narrow edge to the flange, and are evidently designed after the Pennsylvania R. R. section. In English practice, joints with short splice bars and four bolts are practically universal, but for this Australian track six-bolt joints are to be used, and will be an innovation. The bolts will be spaced uniformly 5 ins. c. to c. in angle bars 31 ins. long, this arrangement being in accordance with the tendency of the best modern American practice to use six bolts in short bars. It would seem from the specifications that the rails are to be secured to the ties simply by round spikes, ¾ and ⅞-in. diameter and 4¼ and 5 ins. long under the head. No other form of fastening is referred to, and we are inclined to look upon this as a weak point in the track construction, although the arrangement will be superior to the average American practice in that the spikes are round and driven into holes bored in the ties, while the heads are much heavier than those of our spikes. For the 60-lb. rails the bolts are ¾-in. diameter, and the bolt holes are 1 in. diameter in the rail and 13-16 × 1 1-16-in. in the splice bars. For the 80-lb. rails the bolts are ⅞-in. diameter, and the bolt holes are 1⅛ in. diameter in the rail and 15-16 × 1 3-16-in. in the splice bars. The bolts have the Whitworth thread and are fitted with hexagon nuts, no washers or nutlocks being used, or, at least, not shown on the drawings.

Some notes from the specifications may be of interest in this connection. The ingots from which the rails are to be rolled must be cast from a mixture of the best New South Wales hematite and charcoal spiegeleisen, and the chemical composition of the ingots is to be limited as follows: Silicon, 0.1 to 0.15 per cent.; manganese, 0.8 to 1 per cent.; sulphur not to exceed 0.069 per cent.: phosphorus not to exceed 0.06 per cent.; carbon to be from 0.43 to 0.57 per cent. in 60-lb. rails and 0.55 to 0.65 per cent. in 80-lb. rails. The carbon percentage is higher than has been usual in English practice, and the ores would seem to be low in phosphorus. The proportions may be varied by the engineer in accordance with the results of the inspection of the blooms and rails during manufacture and the tests of the finished rails, so as to secure the most suitable chemical composition. According to the specifications the engineer is given considerable power to harass the contractor in this matter of chemical composition, but unless he is an expert in rail manufacture we imagine that he will be slow to interfere to any great extent if the contractor shows that he understands his business and turns out good rails. Rails that require much cold straightening will not be accepted, and all straightening must be done without hammering. Each rail must be stamped at the end to show from which cast of metal it was made. Certain rails from each day's output will be selected for test, and from each of these will be cut a piece 4 ft. 6 ins. long; this piece being placed head upwards upon iron supports 3 ft. 6 ins. apart. The test piece must withstand two blows from a weight of 1 ton falling 6 ft., the deflection to be not less than 3¾ ins. or more than 4¼ ins.; it must then sustain one blow of the weight falling 12 ft. without fracture. The engineer may change the tests, the main object being to get rails of the highest quality in regard to strength and toughness.

The splice bars call for a higher grade of steel than is common in this country, being required to be made from steel of the same mixture and same chemical composition as the rails, while in this country the bars are usually of a softer steel (with lower carbon percentage) than that of the rails. In this particular detail American practice is mainly inferior to foreign practice. The bars are to be sheared or sawed to length, pressed between dies while hot to take out any bulge, annealed and punched. The splice bolts and the spikes are to be of mild steel, and the bars from which they are made are to stand doubling cold without fracture.

One point of particular importance to the colony will be the relation of the prices for rails as submitted by the bidders for this contract, to those now paid for imported rails, including the cost of freight for the latter. It was stated in the colonial legislature, however, in answer to a question on this point, that there was every reason to believe that bids would be submitted showing that rails could be manufactured at as low a rate as they could be imported. The present price of rails in England is £4 10s. to £4 15s. (say $22.50 to $23.75) per ton, and the freight rates from London to Sydney are 12s. 6d. to 15s. (say $3 to $3.75) per ton. The cost of English rails delivered would, therefore, be about $23.50 to $27.50 per ton. As to wages, we are informed that laborers are paid 18 to 25 cts. per hour, and mechanics about 30 cts. per hour. New South Wales, it may be noted, is practically a free trade colony. The iron deposits have not been worked very extensively, but coal mining is an important industry for home consumption and for export (some of the coal being exported to the United States), and there are large coking plants in operation. There are, we understand, no iron works of any extent now in operation, the field being practically open for the new works to get a good hold of the general iron and steel manufacture.

This is the first time, we believe, that a public invitation has been given for competitive bids for the establishment of manufacturing plants in foreign countries by American capital, but such plants have in some cases been established as the result of private negotiations, the latest and most notable example of this being the new locomotive works for the Russian government at Nijni-Novgorod, which, as noted in a recent issue, are to be designed, equipped and managed by American engineers and American manufacturers. This has undoubtedly resulted from the great success which has attended the extensive introduction of American locomotives into that country. The same reasons have probably had an influence in leading the government of New South Wales to offer to American investors and manufacturers the present opportunity to establish a steel plant and rail mill, and we trust that the matter will be taken up here, and that it may prove to be practicable and mutually profitable for American capital to undertake this enterprise.

LETTERS TO THE EDITOR.

Steel Makers and Chemistry.

Sir: The voluntary introduction of chemical limitations in the revised specification of the Association of American Steel Manufacturers, marks an advance that should not be passed without notice, and the argument that such limitations are valuable and necessary is doubtless nearing a close.

Arguments as to what the chemical limitations should be will now, as heretofore, be in order, and it is to be hoped that engineers will give the matter the attention which it deserves.

The eminent authority on steel, Mr. Wm. Metcalf, in his new book, "Steel," calls the impurities of steel "elements of disintegration," and brings out clearly how, when in sufficient amount, these elements will cause the final failure of a structure. Explanations for the failure of iron and of iron structures, in the past, have been sought for in theories of vibration and shock; had these theories included an investigation of the "elements of disintegration" in the iron, they would have had more satisfactory results.

During the days of iron structures, but little attention was given to its impurities by manufacturers and practically none by engineers, so that we may say that iron has passed without our really having known it.

Phosphorus and sulphur are the most common, the most dangerous, and the most readily controlled of the "elements of disintegration," and it is these two elements on which the A. A. S. M. specification has placed limits. For boiler and fire-box steel this specification limits both phosphorus and sulphur; for structural steel the phosphorus only is limited.

The question naturally occurs, if a sulphur limit is good for boiler plate, is it not also good for bridge steel?

A much used but now threadbare argument has been advanced, that if the engineer took care of the phosphorus the manufacturer could be trusted to take care of the sulphur. This argument was doubtless made in good faith at first, but increased knowledge has shown that the neglect of sulphur sometimes leads to disastrous consequences.

No manufacturer will let the sulphur run so high in his steel that it will break up when he is rolling it, but between this point and safety there is a zone of sulphur in which steel will apparently roll and finish all right, without visible defects, but be filled with invisible cracks which Mr. Thos. Andrews, F. R. S., M. Inst. C. E., calls micro-sulphur flaws.

As sulphur is a hot-shortener it is but natural to assume that when steel is cold, sulphur is no longer to be feared; well and good, if it has not done its treacherous work beforehand. Many failures of steel which have been credited to phosphorus, a thorough investigation would doubtless have shown to be due to "micro-sulphur flaws" alone, or as an able assistant to phosphorus.

Let us thank the American Association of Steel Manufacturers for having given us phosphorus and sulphur limits; not so much for the limits themselves, as for the official recognition that limits are good.

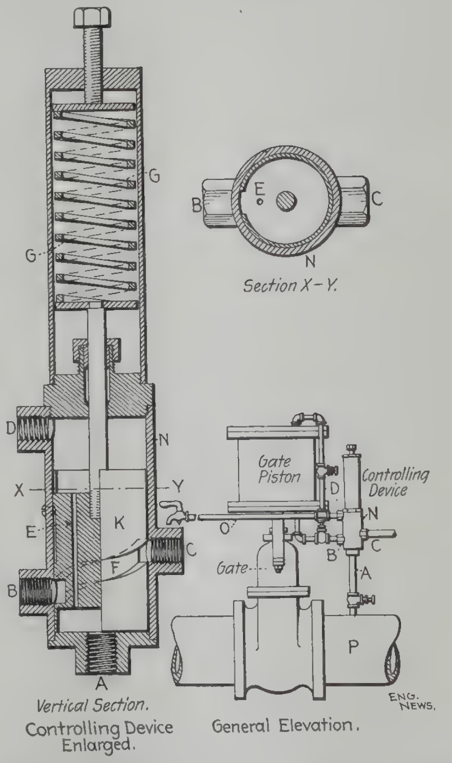
To be sure we must still take, under this specification, for railway bridges, acid open hearth, basic open hearth, acid bessemer, or basic bessemer, straight or mixed, as it may come to us, but in this respect the specifications is no worse than many individual specifications, and in the fact of having chemical limits, it is far in advance of them. A. C. Cunningham, M. Am. Soc. C. E.

Albany, N. Y., Aug. 14, 1896.

(We reprint the revised standard specifications of the Association of American Steel Manufacturers on another page.—Ed.)

A Device for Operating a Gate from a Distance by Hydraulic Power.

Sir: In designing the new gravity system of waterworks recently completed at Astoria, Ore., it was desirable to use a small reservoir, already constructed, for the supply of the low service distribution, although the elevation of this reservoir was insufficient for a first-class fire protection directly from the hydrants, and to construct the new reservoir at such an elevation as to properly supply a higher service, while when connected direct with the low service a suitable fire pressure would be secured. This plan presented the advantages of a moderate pressure for ordinary domestic consumption, and an increased fire pressure when required. The necessity at once arose for a means of readily operating the gates between the high and low services in case of fire; and it was desirable that these gates, two in number, should be both opened and closed from the central fire station. To meet this requirement the writer, in preparing the plans for the works, devised a governor for a piston lift gate, a print of which is enclosed, and which it is believed, will be of interest to many of your readers; inasmuch as this question of operating gates from a distance is one which has attracted some attention, and is often desirable of accomplishment, especially in connection with the use of stand-pipes and direct pressure for fire protection, and to accomplish the speedy closing of large supply mains in case of disastrous breaks.



A Device for Operating a Gate From a Distance by Hydraulic Pressure.

The manner of operation and general arrangement of the parts is as follows: In the cylinder, N, is a close-fitting piston, K, which moves in opposition to the spring, G. The cylinder, N, has provision for four pipe connections, A, B, C and D. Connections B and C freely communicate together by way of the inclined port, F, cut around the piston, when the piston is at the lower end of the cylinder. When the piston is raised the opening, C, is closed, and the opening, B, has free communication with the opening A. The opening D is always unobstructed whatever the position of the piston. A small hole is drilled through the piston longitudinally as shown at E, which gives free communication between the two ends of the cylinder. This hole is drilled of such size as to have a less delivering capacity under the pressure at which the gate operates, than the small pipe extending from the governor to the point from which the gate is to be operated. In operating, A is connected with the pressure pipe in which the gate is placed, a screen being inserted between the main and the governor to prevent the passage of sediment; B is connected with the lower end of the gate cylinder; C with the waste; D with the upper end of the gate cylinder with a tee connection, in one branch of which is connected the line of small service pipe leading to the station from which the gate is to be operated. At the end of this pipe is placed a stop cock or other convenient means of opening and closing the pipe. Under normal conditions this cock is closed, the water has free access from the pipe P through A, E and D to the upper end of the gate cylinder, thus acting on the gate piston and keeping the gate closed. There being an equilibrium of pressure in the two ends of the governor cylinder, the piston remains at the lower end of the cylinder. When it is desirable to open the gate, the pipe at the controlling station is opened, releasing the pressure in D, causing the piston to be thrown to the upper end of the cylinder, which act closes C, and opens B to the passage of the fluid from A, which, acting on the lower end of the gate piston, causes the gate to open while the water from the other end of the gate cylinder passes off through the pipe, O, at the controlling station. By closing the pipe at the controlling station, equilibrium is again gradually restored in the two ends of the governor cylinder through the opening, E, when the spring, G, throws the piston to the lower end of the cylinder, releasing the water from the lower end of the gate cylinder through the openings and movable port B, C and F, while the pressure being again applied to the upper end of the gate piston, causes the gate to close. By reversing the connections between the governor and the gate cylinder, the gate can always be kept open instead of closed while the pipe at the controlling station is kept closed.

This governor has operated perfectly from the very first, and responds instantly to the opening and closing of the cock at the governing station, and the gate operates without production of appreciable ram in the pipes. A check valve placed in the supply pipe from the lower reservoir closes with the back pressure, cutting out the reservoir while the fire pressure is on.

Yours truly, A. L. Adams, M. Am. Soc. C. E.

Astoria, Ore., April 18, 1896.

The "Student" Grade of Membership in Engineering Societies.

Sir: Some time since I saw in an article in a technical journal a reference to "Students of the Institution of Civil Engineers." Would you kindly inform me and several other young engineers, whether these Students constitute men yet in college or young graduates out in life, and in what manner these Students pursue studies under the Institution. Please also let us know if the American Society of Civil Engineers has a Student grade, and if so, how admittance can be had to it. Very sincerely,

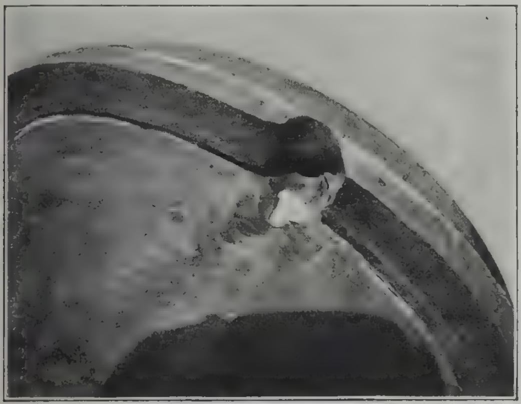
E. L. T.

Baton Rouge, La., Aug. 18, 1896.

[The Student of the Institution of Civil Engineers pursues no regular course of study under the Institution. He is simply entitled to attend the "Ordinary Meetings," to use the library, and to receive a copy of the published papers of the Institution; but he has no vote. He must be over 18 years of age, and be, or have been, a pupil under a Corporate Member of the Institution, under the English system of apprenticeship, or as an articled student of engineering under a practicing engineer. He must be recommended to the Council by the Corporate Member with whom he has served, and unless transferred to a higher grade he loses his connection with the Institution on reaching the age of 25 years. The annual dues are about $10 for a Resident and $5 for a Non-Resident Student. The American Society of Civil Engineers has a practically similar grade of member in its Juniors. This Junior must not be less than 18 years of age and have had at least two years active experience in the practice of some branch of engineering, or have graduated from an engineering school of recognized standing. He loses his connection with the Society upon reaching the age of 30 years, unless meanwhile transferred to a higher grade. His privileges are practically the same as those noted for the Student of the Institution, and both can have acceptable papers published in the proceedings of the societies. The entrance fee of a Junior is $10, with $10 annual dues for a Non-Resident and $15 for a Resident Junior, The purpose in establishing the grades of Student and Junior is to enlist the young men in the aims of these societies, to enable them to profit by the experiences of the elder members of the profession and to give them an opportunity of placing upon record any useful experiences they may have themselves. It is a valuable connection in both cases for the young engineer. By addressing the Secretary of the American Society of Civil Engineers at 127 East Twenty-third St., New York city, any applicant can obtain the constitution and full information on this head.—Ed.]

A Peculiar Break in a Water Main.

Sir: We mail you to-day a photograph showing a peculiar break in a 36-in pipe line. The point on the line where the break occurred is a sandy bottom along the edge of Stony Creek, and the leak was noticed for two months before we had an opportunity to work at it. Upon uncovering we discovered the state of affairs as shown by the photograph, which is unsatisfactory so far as showing the depth of the cutting of the metal is concerned. The pipe was laid in sand free from acids, so that the cutting was not due to chemical action. An attempt was made to cover the orifice with a patch, as will be noticed by the drilled holes, but was not successful, and pieces of two pipes were removed to make a complete repair. When first uncovered the surface of the orifice was brightly polished, and the edges were sharp, showing that the enlargement, at least, of the hole was caused by erosion. The water carried by this line is reasonably free from sand or mineral sediment. Yours truly,



Sand-Jet Effect Upon a Cast-Iron Waterpipe.

A. H. Walters, Secy.

Johnstown Water Company,
Johnstown, Pa., Aug. 20, 1896.

(This is doubtless a case of sand-blast action, the sandy soil furnishing the cutting material and a jet of water escaping from a leak in the joint supplying the power. In the "Transactions of the American Society of Civil Engineers," Vol. VII., page 14, will be found illustrated and described an almost similar case happening in the Philadelphia Water Department in 1878. In the Philadelphia case referred to the water-pressure was about 90 lbs. to the square inch, and a cast-iron pipe ⅜-in. thick was cut through in four days. Mr. Walters does not mention the pressure on the Johnstown pipe, but as the "blast" was in operation for at least two months the result is not remarkable. Judging from the photograph only and the vertical as well as lateral evidences of scour, there may have been several jets at work at the same time.—Ed.)

THE SEWERS AND SEWAGE FARMS OF BERLIN.

In August, 1894, the Prefect of the Seine sent a French government engineer, Mr. F. Launay, to Berlin to investigate the system of sewerage and sewage disposal of the German capital. The report of this engineer, published in the "Annales des Ponts et Chausees," of September, 1895, praises these works highly. The city has a population of about 1,600,000, including the suburbs, and an area of 15,586 acres; in 1874 it was without a sewerage system, while in 1894 the total length of sewers was 462 miles, and over 22,000 acres of land was embraced in the tracts used for purifying the sewage of the city. The construction of the works has been followed by a fall in the death rate from 32 to 20.2 per 1,000. "The most surprising feature in this great work," according to Mr. Launay, "is the rapidity with which it was planned; the methods, once studied out and adopted, have been followed without long or futile discussion with that force of will, that calm perseverance, that strong stubbornness, and, in a word, that spirit of discipline which is marked in the German character.

When the government became convinced that sewerage works were imperatively needed, it sent a commission to France and England to study the methods of sanitation practiced in those countries. Professor Virchow and Director Hobrecht, of the department of municipal works of Berlin, took an active part in this work and the latter was selected to prepare the plans and build the works. His report concluded with a statement to the effect that it was inadmissible to allow sewage to enter the Spree River, which passes through the city, but it should be pumped to irrigating fields in the suburbs; chemical treatment was said to be too costly as well as insufficient.

The city was divided into twelve independent districts, corresponding with slight differences in topography. Each of these basins was called a radial system and was provided in the plans with a system of sewers receiving both storm water and house sewage, and a pumping station for forcing the sewage to the irrigating fields. The part of the city south of the Spree as far as the Landwehr Canal comprises three systems: System I. is at the east, while at the west Systems II. and III. are separated by a line running from the Anhalt railway station to the Spittel market. North of the Spree are Systems IV. and V. To the south of the Landwehr Canal and separated by the Anhalt, Potsdam and Dresden railway stations, are Systems VI. and VII., at the east and west respectively; these also take in parts of Charlottenberg and Schoneberg, which are connected with the Berlin sewerage system by reason of a special agreement between the authorities of the cities. System VIII. comprises the Moabit district at the west of the city, and System IX. extends to the northwest. Finally, Systems X., XI. and XII. extend from the north to the east around the outskirts of the city. The island of Cologne is connected with System III. and the island of Berlin with System IV. The district adjoining the Zoological Gardens is connected with System VIII. by a syphon 282 ft. long, across the Spree. Systems I. to VIII., inclusive, and XII. are now in use; System XI., where the district is not yet built up, has not been begun, and the remaining two are incomplete.

The city is situated on a great sandy plain, with barely perceptible differences in elevation, and on this account the location of the pumping stations was a delicate problem. Wherever possible an attempt was made to select the lowest point in the system in order to give the sewers a grade corresponding with the natural slope of the surface. It was also necessary to keep near the public water ways in order to make as efficient as possible the interceptors which will be explained later. In the outskirts of the city, where the length of the force mains to the fields was reduced, it was possible to adopt less powerful pumps and to reduce in a corresponding measure the expenses of construction and operation. In some cases, the solution of a site for the stations was determined solely by the possession of suitable property for the purpose by the city.

When the location of the pumping station had been settled a system of channels was devised. In fixing upon the maximum of run-off per second from any surface the following assumptions were made: Maximum for household waste, 0.054 cu. ft.; for rainfall, 0.3; or, together, 0.354 cu. ft. per sec. per acre. The sections of the sewers were determined, according to the Eytelwein formula for full pipes. The pumps are all horizontal; and some of the engines are compound, controlling two pumps, and others are single, with one pump. But all the pumps in any one plant are alike in every part. The boilers are all tubular, and the buildings themselves are handsomely furnished and contain lodgings for the inspector and chief mechanic, dining-room, baths and places for drying the clothes of the workmen. The pumps are all of the piston type; excepting for a relay plant in System III., where a centrifugal pump is installed. The pumps in System IX., recently established, are compound machines, making 50 strokes per minute, on the Reidler system.

Each radial system is subdivided into basins, each of which has a collector leading to the lifting plant. The collectors, consequently, have the greatest length and the least fall and receive throughout their course either the direct drainage or the sewage from secondary collectors. The primary branches have the heaviest gradients and the least section. The depth of the water-line, at the head of any collector-system, varies from 4.8 to 8.2 ft. beneath the surface soil; at the pump-well the level is determined by the fall required in the system. At the lifting plant all the collectors unite in a common trunk, which empties into a sand-basin. This basin is essentially a sump, 39.36 ft. in diameter, divided on its diameter, into two equal parts, by a vertical grating of iron bars which leave an open mesh about 0.6-in. square. The velocity of flow in the sewage is checked by the sudden enlargement of the section of channel and by the sand, and the grating catches matter in suspension, which might otherwise clog the pumps. The foot-valve of the pump is placed in the sand-basin on the other side of the grating; or where the arrangement of the pump does not permit this a special channel leads from the sump to the suction pipe.

The sewers themselves, for three-quarters of their aggregate length, are made of vitrified clay pipes ranging from 8¼ to 19 ins. in diameter. The masonry sewers have an ovoid section varying from 2.95 to 6.56 ft. in vertical height. The following table of totals is taken from a full table showing each radial system in detail:

Masonry sewers, length	471,801 ft.
Pipe sewers, length	1,909,429 "
Waste-weirs, masonry	50,623 "
Waste-weirs, pipe	13,307 "
Manholes	2,005
Inspection shafts	8,874
Sewer inlets	14,204

The sewer-inlets or catch-basins, are built of brick masonry and are located about 200 ft. apart on each side of the street, near the curb. They are covered with gratings and admit to the drainage system all the rain falling upon the streets. These basins are cleaned out at regular and short intervals, and the connection between the basin and the sewer is made by a short section of pipe closed by a grating which arrests all floating matter.

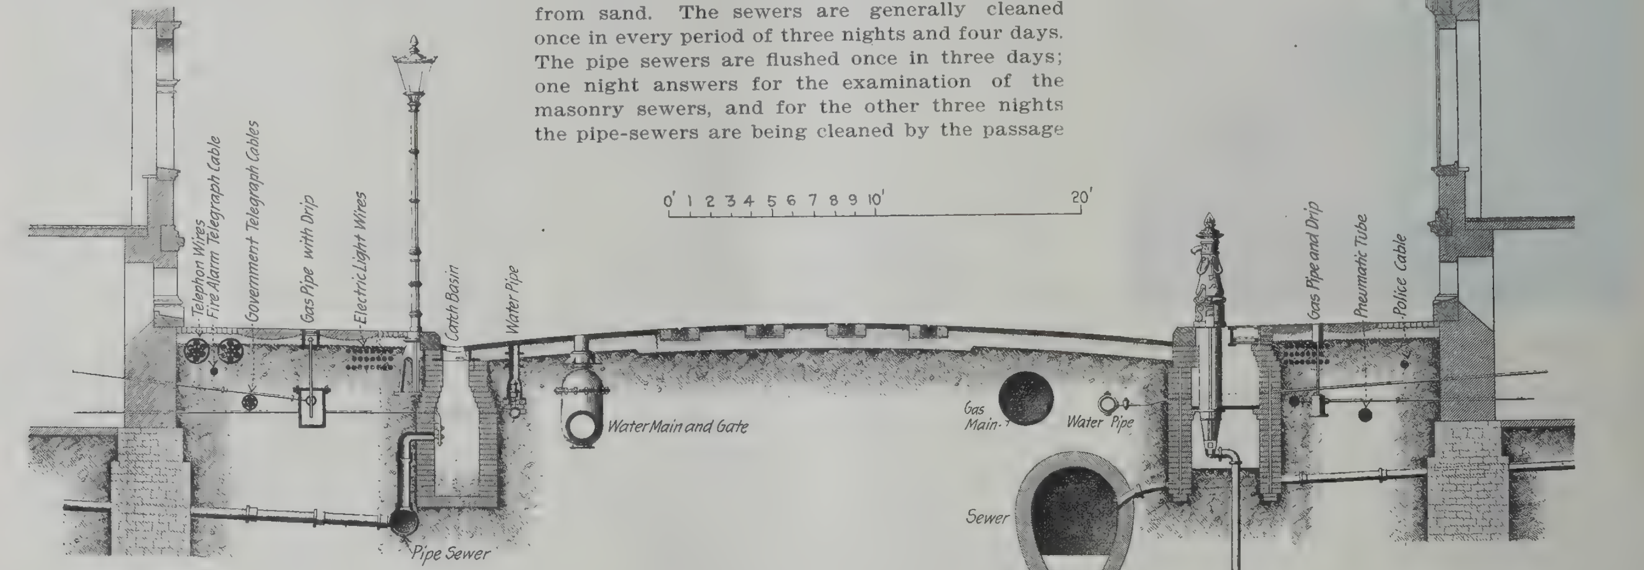
For the purpose of visiting and ventilating the system inspection shafts are placed every 200 or 260 ft. apart, or wherever the pipe sewers change in diameter or in horizontal or vertical direction. These openings are 3.1 ft. in interior diameter, and are so numerous that the whole system can be inspected, flushed and cleaned. The top of these openings is closed at the street surface by a perforated plate; the purpose being to assure air communication between the sewers and the streets. When it is considered that the total capacity of the Berlin drainage system is only 5,300,000 cu. ft. the importance of this arrangement can be better appreciated. During heavy rainfalls the sewers are completely filled and the air is forced out of the perforated plate with violence; but, on the other hand, the accumulation of compressed air at the higher points is prevented, and consequently the drainage back of the water and flooding of certain districts is avoided. The ventilation of the sewage system is also an important end gained.

The waste-weirs referred to connect the sewers with the nearest natural waterway and are used to relieve the sewers in the case of heavy rains. The bottom of these discharge pipes is established on a level with the tops of the pipe sewers, and at the springing line of the ovoid masonry sewers. To prevent a flow from the streams to the sewers this discharge channel is controlled by valves. But as heavy rains are rare in Berlin this relief system is seldom used.

One of the faults of the Berlin system is its small capacity, arranged only to perform mean duty. The Paris sewers, with their very large section, not only can care for all the water coming to them, but also provide a place for water pipes, telegraph and telephone cables and other underground furniture. In Berlin, considerations of economy of first establishment and a reduction in the cost of maintenance prevailed. When the waste-weirs commence to act in that city it is figured that the proportion of household waste to rainfall is 1 to 16; and with a water consumption of 60 litres (16 gallons) per head per day, the proportion of excremental matter is 1 to 100. This corresponds to a dilutation of 1 in 1,600; a rate which descends to 1 in 15,000 when the waste conduits are in full operation.

The pumping mains, leading to the sewage farms, have their upper side buried about 3.3 ft. below the normal street level, and they generally follow the undulations of the surface, having air-valves at all high points, which are opened daily. The diameter of the cast-iron pipe used varies from 2¼ to 3⅓ ft., and riveted iron pipe is employed in crossing streams and railways.

The house connections in Berlin are worthy of note. Building is regulated by a police ordinance of July 14, 1874, and by a municipal ordinance of Sept. 4, 1874. The police ordinance requires every owner of a house to make a connection with the sewers, either by a waste pipe or by a special connection to be used for the water-closets alone. All the old privy vaults have disappeared, and it is forbidden to build new ones. The house owner has six weeks from the date of notice to present to the city authorities for approval a complete plan of the contemplated sanitary appliances to be put in his house; and six weeks after the approval of these plans the installation must be completed.



STANDARD CROSS SECTION OF STREET; BERLIN, GERMANY.

This installation is controlled by the following rules: Every drain-pipe must be trapped and connected with a pipe carried above the roof or ventilated by communicating with a chimney; every sink must be provided with a grating; water-closets must have a water-seal and the pipe is limited to a diameter of 2¾ ins.; upon the direct house connections and directly back of the front wall of the house and between this wall and an automatic valve must be located a water-trap, which can be inspected. Rain-water pipes from the roof must be provided with a grating and a water-trap, so as to retain solid matter coming from the roofing And, finally, special authority is necessary to carry to the sewers any industrial waste or exhaust steam.

The municipal decree orders that the connections under the pavement are to be built by the city at the cost of the proprietors; only the interior work can be put in by the latter. The introduction of water and the sewer connection are obligatory, and each house bordering on a sewerage system pays a quarterly tax, according to its rental value, which is devoted to meeting the interest on the cost of construction and maintenance of the sewers. The amount of this tax is fixed annually by the administration, and in 1894 was 1% on the net revenue from the house.

The actual surface of the city drained by the present eleven radial systems is about 13,210 acres; the streets included represent a length of 314 miles, covering a superficial area of 3,366 acres. The total length of all the sewers, on April 1, 1894, was 450 miles, not including the relief sewers. The number of manholes and inspection shafts together was 10,879, and there were 14,204 catch-basins.

The entire service of maintenance, up to the limits of the sewage farms, is under an inspector having under him a number of special inspectors, the latter usually caring for two systems. The inspector has under his charge at each lifting-plant a chief-mechanic, 3 to 7 enginemen, 2 to 4 firemen, coal-handlers, etc. For the maintenance of the sewers of any system he has from 2 to 4 foremen with 6 or 12 workmen. Each foreman directs three laborers or more, according to the district assigned him. A district includes from 1,000 to 1,200 houses, and from 35,500 to 85,000 inhabitants; it also includes 15½ to 23½ miles of sewers, with 350 to 550 manholes, 450 to 680 catch-basins and from 1,500 to 2,000 house connections. The foreman is responsible for the care of tools, the inspection and cleaning of the sewers, and notes daily the amount of water used in cleaning the sewers and the quantity of sand taken from them. He examines all the house connections and ascertains that they are working properly; he supervises the regular flushing of the sewers and, at night, the cleaning of the same from sand. The sewers are generally cleaned once in every period of three nights and four days. The pipe sewers are flushed once in three days; one night answers for the examination of the masonry sewers, and for the other three nights the pipe-sewers are being cleaned by the passage of a special broom through them. In cleaning the larger sewers, two workmen, provided with boots, are employed; one of these pushes before him with a scraper all the mud, rags, paper, etc., and the second workman follows with a broom and cleans up the invert. These men usually enter at the head of a sewer at 7 a. m., and by 5 p. m. arrive at the sump of the pumping plant. During this time a third workman follows along the street and opens the manhole plates in advance of the two below, thus giving them pure air. It is also usual to have a man at the grating in the central sump to prevent it from being stopped by rags and paper.

The flushing is commenced at the highest point in any sub-system. The flushing tank is filled from the water mains, after the opening leading to the sewer has been closed by a stopper connected with the street by a chain. The tank is emptied at once by pulling out this stopper, and the flushing stream flows on down the system.

The broom-cleaning of the pipe-sewers referred to is done in the following manner: A float with an oiled cord attached to it is passed down one of the manholes into the pipe; to this cord is fastened a tarred cable fixed to a cylindrical broom of "piazzava" fiber which has another cable fixed to the other end, so that if one cable breaks the broom can be hauled out by the other. Two workmen and one foreman draw the broom forward by the aid of a reel; another takes away with a shovel the sand coming to a manhole, and a fourth man manages the rear cable and regulates the flow of distribution water for the cleaning of the sewer. Usually, three brushes of different diameters are used, one after the other, the last having the same diameter as the pipe. The sand is usually removed from the large sewers at night. For this service from 5 to 7 men are required, and the deposit is only removed when it acquires a depth of about 6 ins. One workman shovels the sand into buckets, which are carried by four men, two to each bucket, to the nearest manhole, where two other men lift them to the street.

This somewhat antiquated method of cleaning has of late years given way to an automatic flushing device. This is essentially a dam made of planks and cut to conform nearly to the section of the sewer. This dam is made in sections, united by bolts, for convenience in passing it into the sewer, and is provided with rollers above and below, and is kept in an upright position by a rear brace and guide rollers. It acts as a dam and permits the water to escape under a head through the opening at the bottom, cutting away and driving before it the sand in the sewer. This device is especially servicable in the sewers under 2½ ft. in height into which it would be difficult for workmen to enter. A new device, here illustrated, is also being used in clearing the pipe sewers on a similar principle. In this the plank dam is replaced by a cylindrical dam having a section equal to three-fourths of that of the pipe. To keep the open section down and to guide it, three heavy balls are made to roll in the bottom part.

The description of the sewage farms comes next. As showing the growth of the system of sewage irrigation, it is sufficient to say that in System I. the mean daily delivery was 150,000 cu. ft. in the year 1880-81; in 1893-94, the same system delivered 500,000 cu. ft. daily. In the same period the flow from System IV. increased from 230,000 to 1,253,856 cu. ft. per day. It is interesting to compare the quantity of water actually distributed in the city by the municipal service and the quantity sent by the pumps to the sewage farms. In the year 1893-94 the pumps delivered 2,240,000,000 cu. ft., or 16,800,000,000 gallons of sewage water; about 28 gallons per day per inhabitant. During the same period the average of water distributed from the city mains was 18 gallons per head per day. The extra 10 gallons came from the rainfall and water from industrial establishments originally obtained from wells or from natural streams; and included in this was the solids from the houses.

The natural conditions of the soil acquired by the city of Berlin for its sewage farms are far from presenting the most favorable qualities for purification purposes. The sandy dunes are less permeable than the gravels of the Valley of the Seine, and they rest upon an impervious bed, located at a light depth below them. In fact, the filtering bed is less than 3.3 ft. deep at some places and at no point exceeds 5 ft. The land acquired is in two groups; the first is to the northeast of Berlin and about 1.8 miles from the edge of the city; the second lies to the south and is about 7.2 miles distant. Of the whole 22,230 acres included in these fields, about 78% is represented by irrigation fields. The remainder is taken up by courts, gardens, parks, woods, roads and buildings. Of the total surface, about 70.3% is drained; or 96% of the irrigation area proper. This preliminary drainage is an absolute necessity, owing to the light depth of the filtering bed.

The distribution of sewage over these fields is controlled by a system of cast-iron mains with gates, and secondary conduits, some in pottery and most of them in the form of open drains, buried at least 1.6 ft. and having suitable fall. The principal conduit, leading from the pumping station, abuts at some point on the farm and terminates in a stand-pipe of the same diameter as the pipe. The branches of the distribution pipes terminate at high points and are closed with valves, the diameter of the pipe descending to 10 ins. There are about five of these valves to every 247 acres of irrigated land, and the pipes end in "swan-necks," with the escaping water falling into a circular basin or into trenches. At some places the pipes empty into a rectangular basin, 13 × 40 ft., 6½ ft. deep. These basins deposit the sand and the water in them is made to pass through facines which catch all matter held in suspension.

The beds for "running culture," or for cereals, carrots, potatoes, beans, fruit trees, etc., are arranged as at Gennevilliers (Paris sewage farm; see Engineering News, Aug. 25, 1895), in ridges and furrows. The furrows are from 65 to 98 ft. long; have a width of from 12 to 18 ins. and their depth is from 18 to 40 ins. The ridges thus formed are from 3 to 5 ft., c. to c.; they are generally united in great beds, 20 to 30 ft. on a side and in series of six, with a small dike around them. The prairie or grass beds are usually 200 ft. long by 130 to 160 ft. wide, and they are watered for three or four hours every three days. Certain other basins are set apart for winter use, or for filtration only, no kinds of cultivation being attempted. These basins receive the water in successive beds from 12 to 18 ins. deep, kept in place by dikes.

The experience with the Berlin sewage farms, as at Gennevilliers, proves that there is no burning out of the soil, no swamp-formations, and no necessity for reducing the doses of sewage water at the end of a certain time.

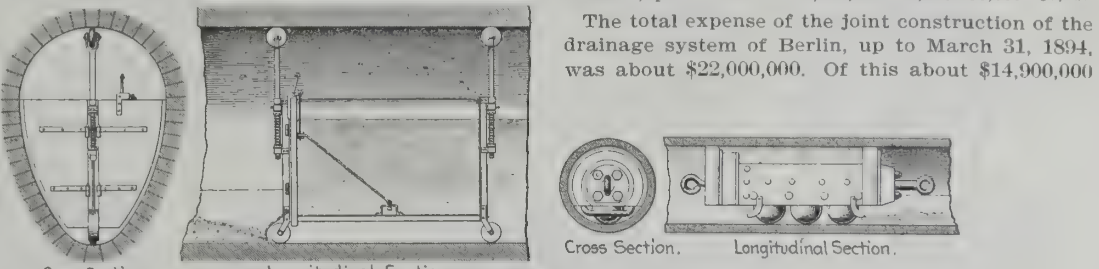
Periodical and methodical analysis will show the constancy of the effluent, or purified sewage, as being clear, pure, inodorous and free from micro-organisms. No epidemic has justified the sinister predictions of the adversaries of sewage farming. The health of the people living on these irrigated fields, carefully controlled by the administration, is always excellent, and the city of Berlin has not hesitated to establish homes for convalescents upon these fields; one at Blankenburg, for 40 women; another at Heinersdorf, for 40 men; a third at Malchon, and a fourth at Blankenfelds. These asylums are recommended by the physicians and are well filled.

As to cost, the following items are interesting: The mean daily wages paid to the workmen are 48 to 60 cts., with lodging, to the foremen of irrigation; 24 to 43 cts. to the workmen who instead of lodging receive 3,000 kilos. (6,600 lbs., or 110 bu.) of potatoes per year, or the land for cultivating them. The occasional laborers receive 36 to 60 cts.; the women, 19 to 24 cts.; and workmen caring for the fruit trees receive 60 to 72 cts. per day. Work is sometimes given as a task, and in this case the daily wages are increased 20 to 50%. At certain points the field work is done by vagrants taken from the houses of correction in Berlin, sent to the fields under guard and lodged in barracks.

The cost of managing the sewerage system in the city of Berlin, for the year 1893-94, was about $14,000; of which $12,900 was for the personnel and the remainder for sundries. In addition to this sum $820 were spent for gaging and $1,565 were set aside for the hospital for sick or injured workmen. The aggregate cost of operating the several radial systems, for the same year, was about $246,000. The average quantity of water taken from each house, etc., for the year 1893-94 is shown in the following summary of a detailed table for each radial system:

Total quantity sewage pumped pr year, gals.	16,343,000,000
Total houses connected with sewers.......	22,611
Sewage water per day per house, gallons ..	1,979
Total number of inhabitants	1,591,791
Sewage pumped per day per head, gallons..	280
Cost of operating, per head, cts.	14
Cost of pumping per 1,000 gallons, cts...	0.934
Total of sewer maintenance and pumping, 1,000 gallons, cts.	1.352

The total quantity of sand and refuse matter of all kinds taken from the drainage system in one year amounts to 130,000 cu. ft. taken from the sumps at the pumping station, and 299,000 cu. ft. taken from the masonry and pipe sewers; a total of 429,000 cu. ft. In relation to the total quantity of sewage water pumped and other solid matter taken from the sewers and the sumps at the pumping-station the dilutation is as about 1 to 5,000. The amount of solid matter still left in the sewage after passing the pumping-station is given in the table of analysis below, as 65 parts per 100,000.



DEVICE FOR CLEANING SEWERS AUTOMATICALLY.

Oval Sewers.

Pipe Sewers.

The improved drainage of Berlin has had an undoubted beneficial effect upon the health of the citizens; and while other factors have assisted in bringing about this better condition, the drainage system seemingly stands first in potency, as is shown by the following table:

Year.	No. houses connected with sewers.	Mortality per 1,000.
1873........	......	30.0
1874........	......	30.2
1875........	57	32.9
1876........	1,025	29.8
1877........	2,014	29.7
1878........	2,415	29.5
1879........	3,602	27.5
1880........	7,478	29,7
1881........	9,867	27.2
1882........	10,468	25.9
1883........	11,968	28.9
1884........	14,100	26.5
1885........	15,895	24.4
1886........	17,395	25.6
1887........	17,955	21.8
1888........	18,479	20.3
1889........	18,984	23.0
1890........	19,898	21.5
1891........	21,352	20.9
1892........	22,012	20.2

Each year the city prepares new land with a view to irrigation; by leveling the surface, tracing out and digging the ditches and irrigation trenches, by building dikes, limiting the beds or basins, and by building roads, etc. Over almost the whole irrigated area the initial drainage of the subsoil is considered very important and absolutely necessary, so as to obtain a filter of sufficient depth. The drains are made of terra cotta pipe, 2⅜ to 2¾ ins. in diameter and ⅜-in. thick, placed end to end and united by sleeves of terra cotta. The water enters at the joints and the lines of drain-pipe are laid about 26¼ ft. apart and they are sunk 5.8 ft. below the surface of the soil; and all abut upon a main drain, about 4 ins. in diameter, leading to an open ditch. Of the total 22,230 acres owned by the city a little more than one-half is now regularly farmed. Some of this land is rented out by the city at a rental of about $20 to $23 per acre, when irrigated; and at $8 per acre when not irrigated or prepared. The total amount of sewage water delivered, in 1893-94, upon 11,542 acres was 16,791,017,000 gallons. This corresponds to 1,455,000 gallons per acre per year, and to about 4,000 gallons per acre per day. The total monthly flow oscillates between a maximum of 1,578,859,000 gallons in July and a minimum of 1,192,070,000 gallons in April.

The table below gives the chemical composition of the sewage taken as it comes upon the farm from the pumps, and three specimens of the effluent taken from the vegetable and fruit farms, the grass lands, and finally from the winter outflow:

(Parts per 100,000.)

		Effluent, from		
	Sewage.	Vegetable farms.	Grass land.	Winter o'tfl'w.
Dry residue	65.00	70.00	80.00	115.00
Loss on ignition	18.00	10.00	10.00	22.00
Residium; ignition test	47.00	60.00	70.00	93.00
Ammonia	6.50	.10	.30	1.70
Nitrites......	.....	.14	1.00	1.35
Nitrates...............	.....	14.00	12.00	1.60
Phosphoric acid	2.00	.....	.10	.14
Sulphuric acid	2.60	4.00	.....	.....
Chlorine	13.00	15.00	17.00	32.00
Potash	4.00	2.00	.....	.....
Soda	12.00	16.00	.....	.....
Bacteria, per cu. cm...	100,000,000	23,000	50,000	60,000

The total expense of the joint construction of the drainage system of Berlin, up to March 31, 1894, was about $22,000,000. Of this about $14,900,000 went for the drainage system and $7,100,000 for the sewage farm, about $4,000,000 of the latter being for the cost of land.

The radial Systems I. to X. and XII., excepting the suburbs of Charlottenburg and Schoneberg, include 22,151 houses, of which 22,091 are drained and united to the drainage system. The corresponding population is 1,563,938 and the amount of sewage removed annually is 16,791,017,000 gallons. From these elements we may arrive at the following conclusions: The cost per inhabitant has been $13.54, of which $9.15 were for the drainage system, and $4.39 for the irrigation fields.

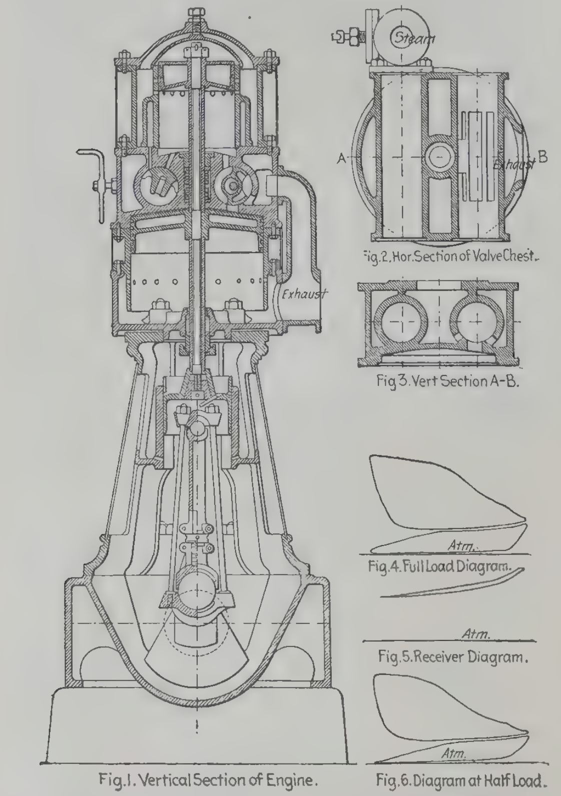
The annual cost of administration and maintenance, the clearing and care of the sewers, pumps and machinery, is $337,000; the maintenance of the sewage farms costs annually $510,000; interest upon capital amounts to $1,046,000, a total annual cost of $1,893,000. The revenue from 22,091 houses amounts to $732,000, and the revenue from the products of the sewage farms is $446,000; a total of $1,178,000. The difference of $715,000 between expenses and revenue is covered from general receipts of the municipality.

The author concludes by comparing Berlin with Paris, as follows: Berlin has not quite 23,000 houses to 1,563,938 inhabitants; while Paris has 82,500 houses to 2,500,000 inhabitants; amounting to an average of 70 persons per house in Berlin and 30 per house in Paris. In Paris, the daily outflow of sewage water is 105,700,000 gallons, of which the excremental matter would amount to 832,000 gallons, or 0.78%. In Berlin, the daily volume of sewage is 45,440,000 gallons, of which the solids represent 520,000 gallons, or 1.14%. While the filtering soil on the Berlin sewage farms is thin, less permeable and only permits an average dosage of 4,000 gallons per acre per day for the whole year, the deep sandy soil of the Valley of the Seine will admit of a dosage of some 11,400 gallons per acre per day.

◆

A NEW SINGLE-ACTING COMPOUND HIGH-SPEED ENGINE.

We reproduce from "Engineering" an illustration of a new vertical single-acting compound high-speed steam-engine, built by the Brush Electrical Engineering Co. (Limited), of London, under patents of their chief engineer, Mr. J. S. Raworth. It is designed especially for direct coupling to a dynamo. Referring to Fig. 1 it will be seen that the high and low pressure cylinders are mounted tandem, the former, which is on top, receiving steam on the up-stroke, and the latter on the down-stroke. Steam is admitted to the upper cylinder by a Corliss valve, and another Corliss valve performs the somewhat complex function of transferring the steam exhausted from the high-pressure cylinder partly directly into the low-pressure cylinder and partly indirectly through the receiver, and also exhausts the steam from the low-pressure cylinder. Fig. 2 is a horizontal section through the center of the valve chests and Fig. 3 a cross section of the chest showing the three parts covered by the low-pressure valve. Figs. 4 and 6 are diagrams taken respectively at full load and at half load, and Fig. 5 is a diagram of the receiver pressure at full load, on double the scale of the steam diagrams.

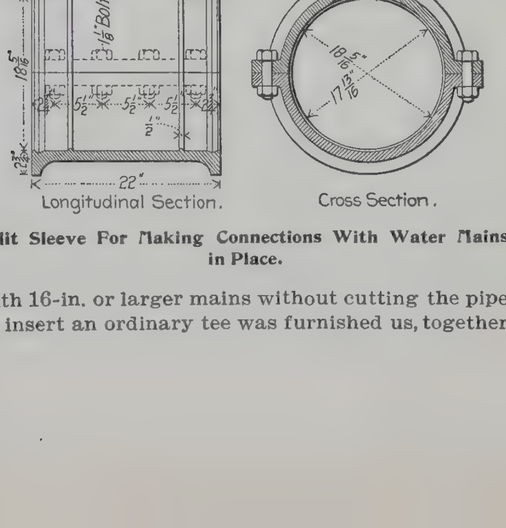


High-Speed Single-Acting Compound Engine. Patented by J. S. Raworth. Built by the Brush Electrical Engineering Co., London.

The bottom of the low-pressure cylinder is always open to the exhaust, while the upper portion of the high-pressure cylinder is in full communication to the receiver, except for a short time when the piston is near the upper end of its travel. Each cylinder has in its wall a ring of holes which acts as a supplementary exhaust. The upper holes, however, pass very little steam, because the pressure in the cylinder when they are opened is practically the same as that in the receiver. The lower ring of holes serves to drain the water out of the low-pressure cylinder. The high-pressure valve is operated by an eccentric under the control of a shaft governor, while the low-pressure valve is worked by an eccentric with a fixed stroke. The mechanical details of the engine contain a number of novelties, the leading idea being to render every part capable of being handled and adjusted by a mechanic of limited skill so that minor repairs may be made without calling in outside assistance.

A SPLIT SLEEVE FOR MAKING CONNECTIONS WITH WATER MAINS IN PLACE.

The following information regarding a special casting used for making 4, 6 and 8-in. connections with 16-in. or larger mains without cutting the pipe to insert an ordinary tee was furnished us, together with the print from which the illustration is made, by Mr. Wm. R. Hill, M. Am. Soc. C. E., Chief Engineer and Superintendent of the Syracuse Water-Works:



Split Sleeve For Making Connections With Water Mains in Place.

> The device is simply a split sleeve with a branch opening. After the main has been partly emptied of water a circular hole of the desired size is cut in the side of the pipe with a chisel. The split sleeve is then bolted on the pipe, and the lead joints are made, completing the connection.
>
> The advantage of this is that the work can be done much quicker and cheaper than to insert a tee. It is unnecessary to entirely empty the main of water, so that there can be no delay if the gates do not entirely shut off the supply as there would be if you were to insert an ordinary tee, in which case the difficulty is often increased by the inability to entirely shut off a section on account of leaky gates.
>
> The trouble of breaking a length of pipe and cutting a new piece to fit in is avoided and there is a saving of two lead joints, a sleeve, and the pipe which would have to be broken. It makes a very substantial connection, in fact a split sleeve tends to strengthen a main.
>
> On the inside of the sleeve there is a bead to hold the hemp, which will insure an opportunity to make a good joint. I would recommend this bead to be on all ordinary sleeves as it will help to make better joints.

On inquiring of Mr. Hill whether he had made use of tapping machines and if so whether he considered this device superior to them, he replied:

> We have several connections that were made by a pipe tapping machine. They have caused us a great deal of trouble and we have been obliged to abandon many of them. The split sleeve with the branch was first used at places where the connections made with the tapping machines were defective. We found the split sleeve to work so nicely that we have adopted them for general use.
>
> I do not wish to be quoted as condemning the machine made joint. I think that they could be strengthened and improved. Our trouble with them is perhaps due to the high pressure. We had them under 95 lbs. They might be all right under a moderate pressure. However, any company or department that could not afford a tapping machine would find it an advantage to use the split sleeve with the branch opening.

WATER CONSUMPTION THROUGH METERED AND UNMETERED TAPS AT LEXINGTON, KY.

A striking argument in favor of the meter system is presented by the accompanying table, showing the water consumption through metered and unmetered taps at Lexington, Ky., for the ten years, from 1886 to 1895, inclusive. The use of meters has rapidly increased in the period until now about 90% of the taps are metered. The table was sent to us by Mr. S. A. Charles, Receiver of the Lexington Hydraulic & Manufacturing Co. Mr. Charles comments on the table as follows:

> We have had some large consumers both on metered and unmetered taps, who have been quite irregular in their consumption, which accounts for the discrepancies in the average; still, the statement points to a constant increase in waste on unmetered taps and a constant decrease on metered taps, and the final average, showing a proportion of more than 4 to 1, may be safely relied on as being less than the present ratio of consumption between metered and unmetered taps.

Water Consumption Through Metered and Unmetered Taps at Lexington, Ky., from 1886 to 1895.

Year.	Av. No. taps metrd.	Metered consumption, Total.	Metered consumption, Av. per meter.	Av. No. not metered	Unmetered consumption Total.[1]	Unmetered consumption Average per tap.

---

[1] These amounts are determined by deducting from total amount pumped the amount used by city, which can be closely approximated, and the amounts used through meters.

[2] In these years 1893, 1894 and 1895, a large and unknown amount of water was used in settling earth filling in public sewers, and the grand or general average for unmetered taps is therefore based on average of preceding seven years.

A GERMAN SYSTEM OF METAL STAIR CONSTRUCTION.

The demand for fireproof construction in all details of modern buildings and the necessarily ornamental role which staircases play in buildings of architectural pretensions, has developed the problem of designing stairways into an important study. In Engineering News of April 16, 1895, the general problem of stair design was discussed in considerable detail, and in the accompanying illustrations a type of metal stair construction is shown which can be profitably studied in connection with this general article. The construction illustrated is of Prussian invention, it being marketed and controlled by the Joly Iron Works of Wittenberg, Saxony, which also holds American patents upon the construction. For the matter from which the illustrations have been prepared we are indebted to the firm named.

Fig. 1 explains the general construction of the stairs quite clearly. The stringers a a' consist of parallel wrought iron bars and are braced by similar bars d d' which extend to support the tread. The separators b b' act as stiffening members, and by means of the interior bolts c hold the whole structure together. The risers, which serve merely to cover the open spaces, are made of sheet or cast-iron wrought in ornamental patterns. They are rabbeted into the separators and have projections to which the treads are fastened. The treads consist of iron plates covered with wood or may be entirely of stone, and are ornamented as may be desired. The railing posts may be fastened to the stringers or the vertical bolts may be made long enough to screw up into the posts.

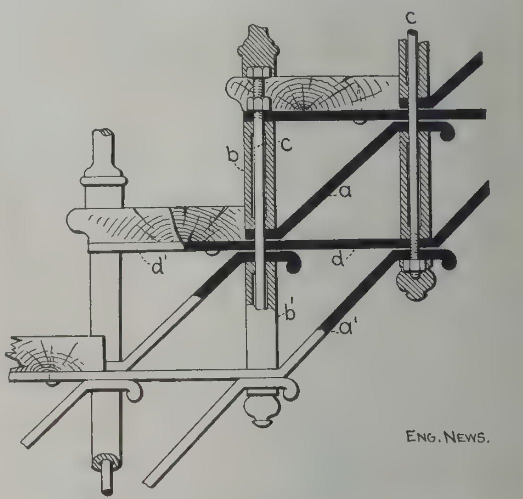

Fig. 1.—Section Showing Construction of Joly Metal Stair System

Joly Iron Works, Wittenberg, Saxony, Manufacturers.

A modification of this simple design is shown applied to a winding stairway in Fig. 2. This illustration shows the light and handsome appearance of the stringers presented by the structural design alone or with only the simplest ornamental finish. In Fig. 3 the adaptability of the construction to profuse ornamentation is shown.

Besides the designs shown, we have received from the manufacturers, circulars showing a number of other very graceful and pleasing designs, which lack of space prevents us from reproducing, but which could be studied with profit, we are sure, by every architect or engineer interested in metal staircase designing. We presume any of our readers can obtain copies of these circulars by addressing the manufacturers.

Among the claims for these stairs are the constructional advantages of having all the tension members of wrought iron, and the total disuse of splices, bolts and rivets, which detract from a neat appearance. It is also claimed, and quite justly, that the stairs in their simplest form produce a decorative effect. The construction is fireproof, or rather non-combustible, since the risers are solid, and the tread even when of wood has a solid iron plate underneath it. According to a circular published by the manufacturers, the construction has already successfully withstood fire in a burning hotel, and is accepted as a fireproof design by the local officials of Wittenberg.

IMPERMEABLE COVERING FOR STONE ARCHES.

In the "Revue Generale des Chemins de Fer," for July, 1896, Mr. Leon Malo treats of asphalt as a protection to stone arches against the infiltration of rain-water. From a general point of view the material used for such protection, says Mr. Malo, should be permanent in character, absolutely impenetrable to moisture and it should be slightly elastic so as to conform without rupture to the inevitable movement of masonry in its normal settlement under construction. This covering should also be able to support, without cracking, considerable weights which must be placed upon it.

In his opinion, asphalt alone, of all available materials, possesses the properties required, and it has been so used for a considerable time. Mr. Malo, however, warns engineers that asphalt must be employed intelligently for this purpose, and he proceeds to describe the difference between mere bitumen and mastic asphalt; and it is the latter he recommends for the use here referred to. The peculiar properties of this mastic asphalt are: That its tenacity is considerable; once cooled it adheres with great firmness to a properly prepared surface, and properly spread in a thin bed it will completely preserve the surface beneath from moisture. When mixed with a certain proportion of gravel, according to the use intended, it becomes very hard and presents an extraordinary resistance to wear.

The surface to be protected should first be covered with a bed of cement, smoothed with a trowel. The maximum inclination of this surface should not exceed 45°. When this cement is dry, pure mastic asphalt, that is without sand, is poured upon this cement in a bed from 10 to 20 mm. (2-5 to 4-5 in.) thick, acording to the importance of the work. This asphalt is spread over the cement at a temperature of 150° to 160° C. If the adjacent surface is still wet the water will at once be converted into vapor, and this vapor will escape in bubbles leaving voids below the asphalt terminating in an extremely fine vent. If it is impossible to wait until the cement bed is perfectly dry before applying the asphalt these bubbles can be smoothed down and the vents closed by applying a hot iron. When the asphalt is cool and hardened care should be taken, in filling over it, to first employ only small material, as large stones thrown upon it will crack the thin crust.

Surfaces inclined at a greater angle than 45°, or even vertical surfaces, can be protected in like manner by using greater care. In covering these steep surfaces the cement coating is purposely left rough and this surface should be perfectly dry before the asphalt is applied. Bitumen is then heated in a kettle to 180° to 200° C., and spread with a brush over the sides to be protected, but with as thin a coating as is possible. Upon this the mastic asphalt is spread with a trowel, or a batten of wood, as in the case of ordinary mortar; but care must be taken that the asphalt is kept in place and smoothed down until it is sufficiently cooled to prevent running. This is delicate work, but when executed with competent workmen and materials of the proper qualities it presents no serious difficulties.

Mr. Malo says that 35 years ago he built a dwelling house upon the side of a hill of calcareous rock, deeply fissured and filled with water at every heavy rain. The foundation wall entered into this soil for 20 ins. and the outside of this wall and the entire area covered by the house was spread with a 1-in. coating of mastic asphalt and sand. The house has always been dry from bottom to top, though the foundations, during heavy rains, are surrounded by a sheet of water from the rain.

The practical employment of asphalt as a covering for the arches of railway bridges dates from about 1858, when Mr. Jules Michel made the first experiments upon the viaducts of the Western Railway of Switzerland. About 1875 the Western Railway of France began to use a bituminous covering and 100,000 sq. m. of this material have since been put in place. Upon the Paris, Lyons & Mediterranean Ry. the viaducts built in 1848 had been protected by a coating of cement; but at the end of 25 years this cement had cracked and it was replaced at great expense, in 1875-78, by asphalt. Other railway corporations adopted the new system and the State also used asphalt largely in the protection of its fortifications. Altogether, says Mr. Malo, the area now protected by mastic asphalt aggregates 30,000 sq. m., and, as far as he can learn, no case of failure has been reported.

On the Eastern Railway of France, between 1887 and the present date about 35,000 sq. m. of the mastic asphalt have been applied to their masonry bridges, and Mr. Malo gives some of these as examples of the work done. The pure asphalt coating used is generally 15 mm. (.675 in.) thick, smoothed with a trowel and following the undulations of the extrados of the arches. The water accumulates in the hollow over each pier and is led through the arch by a metal tubing. Transversely the pure asphalt coating was carried up vertically on the inside of the side walls and at the top was connected with a footway of greater thickness made of asphalt and sand or gravel.

FIG. 2.--VIEW SHOWING WINDING STAIRS CONSTRUCTED ON JOLY SYSTEM.

FIG. 3.--VIEW SHOWING ADAPTABILITY OF JOLY STAIR SYSTEM TO ORNAMENTATION.

As the result of experience Mr. Malo thinks it would be better to apply the asphalt coating in two beds of 10 mm. thickness each instead of in one coating of 20 mm. He finds it exceedingly difficult to insure dryness in the under coating of cement, and the escaping moisture will almost inevitably produce the bubbles and vents before referred to. These vents are very minute, but if sufficiently numerous they will destroy the impermeability of the coating. For this reason he recommends that the first coat be applied as thin as practicably possible, and that a second coating of hot mastic asphalt will then absolutely close the vents left in the first. It is also essential that every precaution be taken to prevent the moisture from penetrating between the asphalt and the bed upon which it rests. In turning up the coating against a vertical side wall it would be well to cut a groove in the vertical wall bevelled from 20 mm., the thickness of the asphalt, to nothing at the bottom. This precaution adds somewhat to the expense, but it contributes in a very considerable degree to the durability and complete impermeability of the covering.

A CAVE-IN OF A SEWER is feared at Long Island City, N. Y., as the engineer of the Improvement Commission, Mr. Van Alst, has reported that an examination of the new large Broadway sewer revealed the fact that the bricks were falling from the top of the arch and that fully 300,000 had already fallen. It was only a matter of time, the engineer reported, when the sewer would cave in, and in its present condition it is very dangerous. A committee was appointed to look into the case, the work having been done and paid for by the former Improvement Board.

◆

INCREASED TRAFFIC ON THE ERIE CANAL is reported by State Statistician Ansel E. Wright. During August more coal was brought into Rochester in one day than in an entire week in 1895. From the opening of the canal to Aug. 20, 1896, 1,244 boats cleared from Rochester, as compared with 1,042 boats in the same period in 1895, and 905 boats in 1894. Detailed statements show that to Aug. 23 the increase of receipts and shipments at Rochester amounted to 60% over the same period of last year. But while the canal business is thus increasing, Mr. Wright intimates that the railways are losing a corresponding amount of trade; for while the canals, in 1895, only carried 58.7% of the total receipts of grain at New York, he expects the canal shipments of 1896 to exceed those of 1894, when they carried 94½% of all the grain sent to New York. Every available canal boat is now being pressed into service.

◆

SUEZ CANAL TRAFFIC, for 1893-94-95, is given as follows in the late report of the British directors of the Suez Canal company:

	1893.	1894.	1895.
Vessels	3,341	3,352	3,434
Gross tonnage	10,753,798	11,283,855	11,833,637
Net tonnage	7,659,068	8,099,175	8,448,383
Transit receipts ...francs	70,667,361	73,776,827	78,103,717

Of the ships using the canal, Great Britain owns about 2,400 out of the total, and Germany, France and Holland come next, in the order given; though German ships have increased from 272, in 1893, to 314, in 1895. This canal was opened to traffic in 1869; in 1872 1,082 vessels passed through, with a gross tonnage of 1,744,481 tons, yielding transit receipts of 8,993,732 francs. In 1880 the number of vessels rose to 2,026, and in 1882 to 3,198, and since the latter date the number has never fallen below 3,000. But while the mean net tonnage per vessel was 1,071, in 1872, this mean tonnage was 2,460 in 1895. The average duration of voyage is now 18 h. 44 min., for vessels navigating by night as well as by day; and the average for all vessels is 19 h. 18 min. In 1895 3,266 vessels navigated the canal by night and day. Since April 15, 1890, vessels drawing 25 ft. 7 ins. have been permitted to pass through the canal.

◆

THE BAZIN "ROLLER-STEAMER" has been launched at Paris. This craft is essentially an iron box 120 ft. long, 40 ft. wide, and 5 ft. deep, mounted upon six lenticular hollow disks or rollers, each 30 ft. in diameter and sinking into the water 10 ft. The machinery, of 750 HP., is contained in the box, and operates a screw and the six rollers, which latter pierce the box. M. Bazin expects his strange looking ship to roll over the water instead of cutting through it, and aims primarily at a vast increase of speed and an economy of fuel. He also asserts that its stability will be greater and the craft safer against danger at sea, as two rollers would keep it afloat. He proposes to navigate his ship down the Seine and across the Channel at an estimated speed of about 30 miles per hour.

◆

THE EXPLORING STEAMER "FRAM" has arrived safely at Skjervoe, near the North Cape. The captain telegraphs that he drifted to latitude 85° 57′ N., almost as far as Dr. Nansen traveled after he left the "Fram," in August of 1895. All were well on board, and a deepest sounding of 13,110 ft. and a lowest temperature of 52° below zero are reported.

◆

A FLOATING STATION for the U. S. Life-Saving Service is to be anchored in Boston Harbor. It is a triangular craft, 100 ft. long, 33 ft. beam at the stern and 12 ft. deep. The lifeboats are swung inside, on each side of an opening 20 ft. wide which extends inward from the stern for a distance of 30 ft. This is roofed over and here the boats can be easily launched, the vessel being anchored by the bow so that the boats will row off under the lee of the floating station. The vessel was designed by Mr. Kimball, Superintendent of the U. S. Life-Saving Service.

◆

THE AIR-SHIP OF CHARLES H. LAMSON made a very successful ascension at Portland, Me., on Aug. 20, and aerial experimenters declare his achievement the greatest step yet made towards solving the problem of aerial navigation. The "air-ship" used was really a box-kite made of two oblong boxes, parallel to each other and connected at the middle. It is the Hargrave ship with improvements by Mr. Lamson, tending to improve the steering qualities by hinging the rear cells of the boxes, etc. The ship was provided with a dummy weighing 150 lbs. seated in the car; it was secured by a line tested to a pull of 500 lbs., and when the forward end was slightly lifted and a short run taken it ascended steadily and safely to a height of about 600 ft. At this point a sudden gust of wind broke the cord and the ship sailed on for about half a mile and then gently descended. Had a man been in the car to attend to the steering apparatus Mr. Lamson claims it would have safely ascended to a still greater height, and as easily descended.

◆

AN AIR SHIP OR NAVIGABLE BALLOON is being built by Cusab Bros., of Walkerton, Ind. The balloon is cigar-shaped, 15 ft. long and 4 ft. diameter, with one propeller at the rear and two at the front. A car is suspended below the balloon.

◆

TWO MAIL-COLLECTING AND SORTING WAGONS are being built at Hartford, Conn., for the post office service. Each wagon has a body 12 ft. long by 5 ft. wide, and 6½ ft. high, which is fitted with all conveniences for sorting, cancelling and pouching the mail as fast as collected. Two horses will be used with each wagon, and there is room for two clerks inside. It is proposed to make collections continuously, the carriers emptying the street-boxes and bringing the mail to designated points on the routes. It is estimated that from two to three hours can be thus saved in sending mail to its destination, as compared with the old system requiring all mail to be first sent to a main sorting and distributing center.

◆

BICYCLES ARE TAXED IN FRANCE at the rate of 10 francs, or $1.93, per annum. The popularity of the bicycle in that country is thus indicated in the national tax-collector's reports. This tax was imposed on April 29, 1892, and now 160,000 machines are on the tax-lists. "Le Matin," of Paris, estimates that there is now in use one bicycle to every 250 persons of the population of France; and if the aged, young children and the majority of women be excluded, there is one bicycle to every 50 persons who can ride.

◆

A STORAGE BATTERY ELECTRIC CAR, built by the Electric Storage Battery Co., of Philadelphia, is to be tried on the 34th St. branch of the New York elevated railway.

BOOK REVIEWS.

THE ENGINEERING INDEX.—Volume II., 1892-1895. Edited by J. B. Johnson, C. E., Chairman Board of Managers, and Manager of the Index Department of the "Journal of the Association of Engineering Societies." Associate Editors: F. E. Turneaure, C. E.; C. B. Stewart, C. E.; J. L. Van Ornum, C. E. New York: The Engineering Magazine. 8vo.; pp. 474. $4.

As a labor-saving device this index ranks high among the aids to the engineer. In fact, it does more than save him labor; it points him to sources of information which it would be next to impossible for him to discover for himself.

The matter indexed, as many of our readers know, is that appearing in the leading engineering and allied periodical publications of the world. The index originally appeared in the monthly numbers of the "Journal of the Association of Engineering Societies" during the past four years, and is here brought together in convenient form. Vol. 1. was published in 1892, and covered the period from 1884 to 1891, inclusive, so that the two volumes include what has appeared in the engineering periodicals for the past eleven years. For the convenience of our readers it may be stated that copies of the first volume can still be obtained from Mr. John C. Trautwine, Jr., Assoc. M. Am. Soc. C. E., Secretary of the abovenamed association, 257 Fourth St., Philadelphia.

For many years the index work carried on by Professor Johnson was the only thing of the kind, for engineers, but lately the "Engineering Magazine" has been covering about the same ground. This fact finally led to an arrangement by which the journal was to publish Professor Johnson's index for the past four years in one volume, and bring out a yearly volume of a similar nature, the index in the "Journal of the Association of Engineering Societies" to be dropped after the close of 1895.

The volume before us, like its predecessor, aims to be more than an index, in that it gives under many of the entries some idea of the nature and extent of the article, thus enabling the user to decide, in some cases, whether the article contains the particular information which he desires.

While we cannot speak too highly of the usefulness of this volume, yet it has its faults, and they are serious ones. They relate, however, not to the matter included, nor the comments upon the articles indexed, in all of which most excellent judgment seems to have been used. The greatest fault of the book is that after the matter for it was extracted from the various sources, assorted into classes and the classes arranged alphabetically, the work was then to a large extent stopped, without making any logical arrangement of the matter in each class.

Where the number of entries under a given subject are few, like copper, dredging or flume, this matters little to the user, although none the less bad indexing, but when one wishes to find something under boilers, which occupies eleven pages, or bridges, with 25 pages, or railroads, with 32 pages, much time must be spent which might have been, and should have been, saved if the indexer had carried his task to its logical conclusion. To make this plainer, let us take up boiler explosions. There are two references to this subject on page 24, three on page 25, one on page 29, two on page 30, one on page 31, and four on page 32, and in most cases the entries on one page are separated. Or, instead of a general subject like boiler explosions let us take a specific structure of note, as the Memphis Bridge. Bridge and bridges together extend from page 38 to page 63, and there are ten entries relating to the Memphis Bridge on eight different pages beginning with the first page devoted to the subject, and ending with the twenty-first, thus: one entry each on pages 38, 46. 53, 54, 56 and 58, and two entries each on pages 45 and 57.

The criticisms thus far made are for sins of omission, rather than commission. Further criticisms relate to matters of judgment connected with the art of index-making, instead of the failure to complete the task in all its details.

The classification of subjects seems to overlap greatly in instances that cannot at all be classed as cross-references. Under "Railroads" are entries on electric and elevated roads, but both these sub-heads have their own place in the book, to which reference must be made, as well as to railroads, to find all that has been published on these subjects.

The references from one subject to another throughout the work, while in many cases valuable, seem carried to excess. Thus under "Iron" we are told to "see" alloys, bridges, buildings, iron and steel, cast iron, wrought iron and numerous other subjects, 28 in all, some of which are merely sub-divisions of the subject and should have appeared under it, instead of being scattered through the book. These lists are often placed at the middle of the section, instead of at the beginning or end, as would be expected.

No one should be deterred from securing this valuable reference book because it does not accomplish all it might when it has done so much to lighten the labors of the engineer and point out sources of information, the mere existence of which he would not and practically could not otherwise know.

GENERAL SPECIFICATIONS FOR STEEL HIGHWAY BRIDGES AND VIADUCTS.—New and revised edition, 1896. By Theodore Cooper, Consulting Engineer. 8vo.; pp. 25; 25 cts.

The last edition of the highway bridge specifications was published in 1890, but since then methods of manufacture and construction have been improved and modified, and conditions of traffic, as affecting loads on street and highway bridges have been changed. This new edition of the specifications has therefore undergone several important changes and modifications. Iron has been left out altogether, as in the new railway bridge specifications, and the classification and requirements of steel there given have been adhered to. In the arrangement of different classes of bridges important changes are noticed. It has been found necessary to provide five different classes for varying requirements of traffic and loading, instead of only three, as in the former edition. Class A 1 is entirely new, calling for a buckle plate floor with regular street pavement, an addition certainly needed in view of the growing demand for substantial bridges in the larger cities, furnishing, in fact, an unbroken street surface. One of the most important changes, which will have an influence in materially improving the safety and reputation of highway bridges, is in the provision for loading. The enormous growth of electric railways with cars far heavier and speedier than the old-fashioned horse cars, and frequently exceeding in weight all other classes of vehicles, has occasioned important changes in the loading provided for the other classes, both for suburban and town bridges. The light loads are thus left for comparatively unimportant country bridges, where there is no probability of electric railway construction, and where the loads from other sources are relatively light. The allowed tensile strains on truss members are practically the same as they were before for medium steel, but the allowed strains on floor beams and stringers have been reduced from 14,400 to 13,000 lbs. per sq. in., and the unit strains on floor-beam hangers have also been reduced. This reduction of the unit strains on members of the floor system is undoubtedly made in consideration of the electric car traffic, with high speed and frequent application of the loads. The formulas for unit strains on compression members have also been modified, especially those for posts. A special formula has been given for posts of deck bridges and trestles, allowing higher strains than on posts for through bridges. The chapter dealing with details of construction is in all essential features the same as that of the railway specifications, with some minor changes in the requirements for minimum thickness of metal, size of lattice bars, etc. As to workmanship the two specifications do not differ.

THE BENDING OF RAILS IN THE TRACK by locomotives with faulty counterbalancing has recently been discovered on the Louisville & Nashville R. R. The rails were bent sidewise and not vertically, as is usually the case when the counterbalance is too heavy, and there seemed to be no bending action produced by the driving wheels until the speed was over 48 miles an hour. The bends were produced first at one side and then at the other, evidently by alternate blows from the sides of driving wheels. It was found that the main driving wheels were about 600 lbs. short of the correct weight for counterbalance, and this weight was distributed between the back and front wheels of the engine. This caused an oscillating motion, and the driving wheels rocked from side to side. By using lead, the proper weight was put into the main driving wheels, and the extra weight was then taken out of the other wheels. This resulted in stopping the evil effect upon the track.

◆

SOME TWO-CYLINDER COMPOUND LOCOMOTIVES, of the consolidation type, have been built by the Pittsburg Locomotive Works, of Pittsburg, Pa., for the Lake Superior & Ishpeming Ry. The compounding system adopted by the Pittsburg Locomotive Works was described in our issue of Jan. 2, 1896, and the following are the dimensions of these new engines:

Driving wheels, diameter	4 ft. 8 ins.
Driving-wheel journals	8 × 9 "
Wheelbase, driving	15 ft. 6 "
" total engine	23 " 6 "
" engine and tender	15 ft. 10½ "
Weight on driving wheels	132,800 lbs.
" total, engine	147,600 "
" of tender, loaded	76,200 "
Cylinders, h. p.	20 × 28 ins.
" l. p.	31 × 28 "
Boiler, straight, diameter	5 ft. 7 "
Boiler pressure	180 lbs.
Tubes, 240; diam. 2¼ ins.; length	14 ft. 7 ins.
Firebox	9 ft. 0 ins × 3 ft. 6⅜ "
Grate area	31.78 sq. ft.
Heating surface, tubes	2,049.50 " "
" " firebox	148.60 " "
" " total	2,198.10 " "
Height, rail to smokestack	14 ft. 11¼ ins.
Coal capacity of tender	280 cu. ft.
Water capacity of tender tank	4,000 gallons.
Fuel	Bituminous coal.
Brake fittings	Westinghouse-American automatic.

◆

RECORDING TURNSTILES are being tried at some of the less important stations of the New York elevated railways, to avoid the expense for tickets, ticket sellers and ticket choppers. One man takes the fares and releases the clutch of the machine, allowing the arms to revolve as the passenger pushes against them. The machine is locked at each quarter of a revolution and registers the number of revolutions. The machines have been in use on the Brooklyn Elevated R. R. for some time. They are manufactured by the American Passimeter Co.

◆

THE KINGS COUNTY ELEVATED RY. CO., of Brooklyn, N. Y., was placed in the hands of a receiver on Aug. 31, Gen. James Jourdan, the President of the company, being appointed to that office by general consent. This road was chartered in January, 1879, but owing to litigation construction was not commenced until 1886, and the first three miles of the railway were opened to traffic on April 24, 1888. On Aug. 20, of the same year, 4½ miles were in operation. The Fulton Elevated Ry. Co. was then organized to extend the road to Jamaica, and it was leased to the Kings County Co. for 99 years and completed in July, 1894. In 1895 the company was reorganized, absorbing the Fulton elevated railway, and its capital stock was increased from $3,250,000 to $4,750,000; both first and second mortgage bonds were issued at the rate of $550,000 per mile of road. The Brooklyn & Brighton Beach Railway was leased in December 1895, The cause given for the failure is the great decrease in revenue due to the competition of the trolley surface roads.

◆

ELECTRIC TRACTION on the Nantasket Beach Branch of the New York, New Haven & Hartford R. R. was in June last extended as far as East Weymouth in the direction of Boston, on the main line of the Old Colony Division. On the new line, however, the overhead conductor is not used. A third rail laid between the rails of the surface track takes the place of the trolley wire, and the cars have been regularly operated over it between the regular steam trains without hitch or difficulty. In the operation of the cars the change from the overhead trolley to the third rail source of power is made imperceptibly. When the car approaches the end of the trolley wire a knife switch under the hood of the car is closed connecting the shoe beneath the car with the motor circuit; the trolley slides off the overhead wire and is hooked down, the car meanwhile continuing on its journey. On the day of the inauguration of the third rail section several high speed spurts were made, and these have frequently been exceeded in the actual service. The first section, with overhead trolley wire, was described and illustrated in our issue of Aug. 1, 1895. The overhead wire and third rail sections were both built by the General Electric Co. The car house has four pits over which the cars may be run for examination of the motors and is fully equipped with all the necessary appliances.

◆

IRON CAR-TRANSFER BRIDGES are being placed at certain points along the water front of Brooklyn, N. Y., in connection with the new dock railway system of the Brooklyn Wharf & Warehouse Co. Each transfer bridge has two through trusses, 100 ft. long, 33 ft. wide and 9 ft. deep, and weighs about 120 tons. The river end will be supported by a wooden pontoon, 40 × 30 ft., 7 ft. deep. The bridges are built on the ground by the Elmira Bridge Co., of Elmira, N. Y.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week was the derailment of the southbound White Mountain express, of the Boston & Maine R. R. at Concord N. H., Aug. 27. The train was entering the yard at a speed of about 30 miles an hour when it was derailed by a defective switch, the engine and tender were upset and fell over on their sides, and the heavy baggage car telescoped the smoking car for half its length. None of the other cars were badly damaged. Nobody was killed outright, but fifteeen persons were injured, some seriously. ——A rear collision between a westbound special freight train and a newspaper express occurred Aug. 30 at Orange, Mass., on the Fitchburg R. R. The freight train was ahead, but had broken apart while east of Orange, and as the delay made it impossible to reach Erving, where it had orders to let the express pass, the train was trying to reach Orange to cross over to the eastbound track. It did not reach the crossover in time to avoid the collision. The engine of the express smashed and derailed twelve cars and then left the track and fell over on its side, the engine and one passenger car being wrecked. The engineman and fireman were killed.

◆

A GRADE CROSSING DERAILMENT occurred Aug. 19 at Columbus, O., at the crossing of the Ohio Central Ry. and the Cleveland, Cincinnati, Chicago & St. Louis Ry. The tower man gave a clear signal for a train on the former line and then changed it to danger in the face of the train, with the result that the train was derailed by the derailing switch, but nobody was hurt.

◆

THE SOUTH HALSTEAD ST. LIFT BRIDGE over the Chicago River at Chicago, Ill., was raised on Aug. 25 while an electric car was crossing. The signals were not displayed to stop the car, but the engineman claimed that a steamer was so close to the bridge that he had to raise it to avoid an accident. The passengers were considerably scared, fearing that the car would run off the end of the bridge span. The matter has been made the subject of an investigation.

◆

THE FALSEWORK OF THE MISSION ST. BRIDGE over the Spokane River, at Spokane, Wash., gave way Aug. 25, and five men were injured. The men were raising some of the supports at the pier when the falsework broke loose from these supports and fell over.

◆

A POWDER EXPLOSION occurred at the dryhouse of the Miami Powder Works, five miles from Xenia, O., Aug. 26, and two men were killed. The men were in the dryhouse when the 30 tons of powder in the building exploded.——An explosion of 5,000 lbs. of giant powder occurred Sept. 1 at the Equitable Powder Mills, Alton, Ill., by which three men were killed.

◆

A FIRE AT ONTONAGON, MICH., on Aug. 26, practically destroyed the town, which had a population of about 2,000, and a number of people are thought to have been lost. An immense amount of lumber was destroyed, and the water-works plant and government breakwater were badly damaged, while the great works of the Diamond Match Co., valued at $1,000,000, were destroyed. The town is in the copper mining district and is the Lake Superior terminus of the Chicago, Milwaukee & St. Paul Ry.

◆

THE COST OF THE NEW EAST RIVER BRIDGE is placed at $7,510,000 by the Chief Engineer, Mr. L. L. Buck, M. Am. Soc. C. E., in his statement to the Commission. It will require this amount to complete it by Jan. 1, 1900. The amounts estimated for the several parts of the work is given as follows:

Description of work.	Cost.
New York tower foundations	$500,000
Brooklyn tower foundations	860,000
New York anchorage	820,000
Brooklyn anchorage	820,000
New York tower, steel	186,000
New York tower, erection	124,000
Brooklyn tower, steel	186,000
Brooklyn tower, erection	124,000
Cable strands	450,000
Cable erection	300,000
Suspended superstructure, steel	966,000
Suspended superstructure, erection	644,000
Approaches, steel	780.000
Approaches, erection	520,000
Flooring, painting, &c.	230,000
Total	$7,510,000

◆

THE HARLEM VIADUCT of the New York Central R. R. will not be opened to traffic before the end of this year, or perhaps next spring, according to the Chief Engineer, Mr. Walter Katte, M. Am. Soc. C. E. The reasons given are an injunction affecting the proposed Harlem station, and a law passed through the Legislature compelling the company to change its plans for the station at 125th St. The new station is to be under the structure, in the center of Park Ave., and it will cost about $95,000. The four-track drawbridge over the Harlem River and the approaches on both sides are completed and the tracks are already laid.

◆

AN ELECTRIC DREDGE has recently been built by A. F. Smulders, of Rotterdam, Holland, for service on the Esla River, in Spain. It is a ladder dredge, and a 45-HP. motor running at 600 revolutions per minute drives the dredging chain, although the average power required is only 15 HP. The hoisting engines for operating the spuds are operated by motors, as are also the screws. the drums for raising and lowering the dredging chain, and a centrifugal pump. On the river bank is a power house with three-phase alternating dynamos delivering the current of 2,000 volts, which is transformed on the dredge to 200 volts. This plant also furnishes current for the motors which operate a discharging plant, which elevates the dredged stuff from the scows and loads it into railway cars.

◆

THE DUPLICATE STEEL SUPPLY MAIN for the water supply of Newark, N. J., is practically all laid. It is 21 miles long, 48 ins. in diameter for about five miles and 42 ins. for the remaining distance. It parallels the 48-in. steel main put in use in 1892, but was laid in less than half the time taken in putting down the first one. Some trenching was done as early as the latter part of December, 1895, and pipe laying was begun in March, 1896, but none of the work, it is said, was pushed until April. The work has been done by the East Jersey Water Co., of which Mr. Clemens Herschel, M. Am. Soc. C. E., is engineer, with T. A. & R. G. Gillespie, of Pittsburg, Pa., as contractors. The same contractors laid the original pipe line.

◆

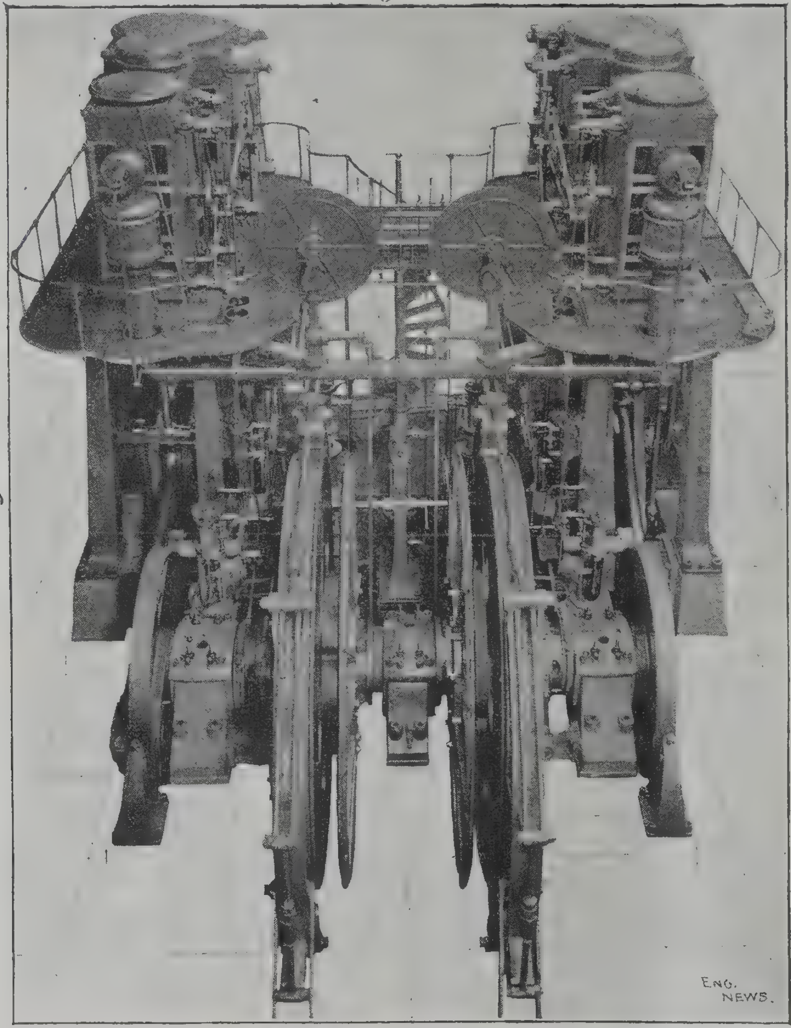
BIDS FOR PUMPING MACHINERY with a capacity of about 23,800,000 U. S. gallons are wanted by the Sanitation Board of the City of Mexico until Nov. 14. There may be one or more pumps, with a guaranteed duty of about 100,000,000 lbs. per 100 lbs. of Cardiff coal. Water tube boilers are required. The delivery from the pumps will be through a 42½-in. pipe, with an initial pressure of 17 lbs., water to be taken from a reservoir with a constant water level 5 ft. below "the level of the soil." The water pumped will be used for sewer flushing. Mr. Roberto Gayor, M. Am. Soc. C. E., is city engineer and Mr. Jose Ives Limantour is Chairman of the Sanitation Board of the City of Mexico.

THE GREAT HOISTING ENGINES FOR THE ANACONDA COPPER MINING CO.

Many of the large and deep mines in this country require very large and powerful plant for hoisting and pumping, and we illustrate, this week, two immense hoisting engines which have recently been built for the Anaconda Copper Mining Co., of Butte, Mont., by the Union Iron Works, of San Francisco, Cal. These engines were described to us during a recent visit to these works, and we are indebted to Mr. H. T. Scott, President of the Union Iron Works, for photographs and particulars of the engines, which have been named the "Aztec" and "Modoc." The larger view shows the engines in the erecting shop, at San Francisco.

Each pair of engines consists of one left hand and one right hand compound beam engine, connected to the reel shaft by disk cranks with crank pins set at right angles.

The cylinders are vertical and inverted, each engine having one high pressure cylinder, 26 × 72 ins., and one low pressure cylinder, 46 × 72 ins. The pistons are connected to opposite ends of the beam by piston rods, crossheads, and reach rods, or links. At the top, or king post, of each beam, one of the main connecting rods take hold, while the opposite end of the rod is connected to the crank pin, thus giving at all times a positive stroke of 72 ins. to the pistons.



END VIEW OF HOISTING ENGINES FOR THE ANACONDA COPPER MINING CO.
Union Iron Works, San Francisco, Cal., Builders.

The high pressure cylinder is located in front of the low pressure cylinder and a reheater is placed between them. The high and low pressure cylinders are steam jacketed, and the water of condensation is automatically carried off from the jackets by steam traps, which discharge into feed tanks or condensers. The cylinders of each engine are supported by a cast-iron framing, consisting of four vertical and four diagonal columns, resting on a heavy bed plate and securely bolted thereto. All the cylinders are covered with teak wood lagging, and have highly finished metal covers.

The main valves of each engine will be of the Corliss type, worked by a wrist plate, which derives its motion from an eccentric on the reel shaft, and a crank on the beam pin. The valve motion is a modification of the Walschaert valve gear. The reversing gear is operated by a separate engine and hydraulic controlling cylinder. The cut-off valve gear mechanisms on the low pressure cylinders are adjustable by a hand lever or governor, as desired, and the cut-off valve gear mechanisms of the high pressure cylinders are controlled by a governor and by a hand lever on the working platform.

The beam center bearings and the main bearings for the crank shaft are cast in and form a part of the main sole plates. All the bearings are substantially fitted and provision is made for adjustment to allow for wear of the moving parts.

There are two reels or drums on each crank shaft, each having a capacity of about one mile of flat wire rope. The reels may be operated independently of each other or in balance as desired. Each reel is fitted with a patent friction band clutch applied by an entirely separate engine, and hydraulic controlling cylinders. The reel brakes are of the Post pattern, with beams of heavy cast iron, securely braced with steel rods, tied together top and bottom. Each is operated by a separate engine and controlled by hydraulic cylinders.

The auxiliary engines for working the reel brakes, reel clutches, reversing gear, and disk brakes, are operated by hand levers, all grouped conveniently together on the operator's platform, which is located between the engines, and forms a part of the main engine gallery. There are eleven separate engines to each pair of these hoisting engines.

To the end of the rope on each reel is secured a four-deck cage, which when loaded and in full motion in the shaft will travel with a velocity of 40 ft. per second. Each reel is provided with a very ingenious rig for indicating the position of the cages in the shafts, and the speed at which they are traveling.

A governor is fitted to each pair of engines, which, when at full speed, assumes entire control of them, giving a uniform speed to the cages, and regulating the valve-gear tripping mechanism to cut off at the most desirable portion of the stroke, which means an economical distribution of steam in the cylinders and an economy in fuel consumption.

There is one main central winding stairway leading up to the upper gallery or operator's platform, with numerous smaller platforms, giving access to all the parts of the engines requiring constant attention and adjustment. The platforms are provided with iron stanchions, capped with brass hand railing, neatly designed and highly polished. Brass drip pans are provided to catch any waste oil from journals, and all piping used around the engine is of brass.

To work one pair of these engines in all their requirements, the man has seven levers and one foot lever to operate, while just in front of him are located the two dials or indicators, which require his constant attention while the cages are in motion.

Each pair of hoisting engines weighs about 400 tons, and the rated power of the two sets of engines is about 5,000 HP. The engines are said to be the largest of their kind in the world

---

NOTES OF A TRANSCONTINENTAL TRIP.

(Editorial Correspondence.)

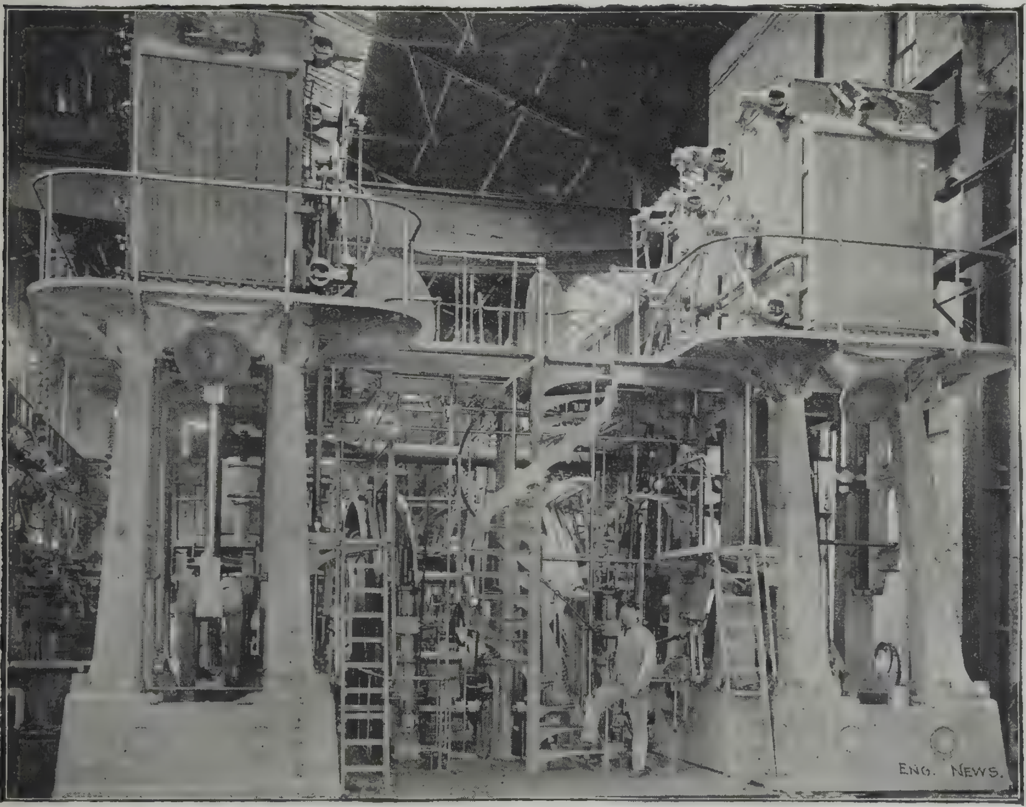
I.

It had been my intention to attend the annual convention of the American Society of Civil Engineers, held in June, at San Francisco, Cal., and to accompany the party on the special train from New York. Circumstances, however, prevented this, but as all preliminaries had previously been arranged it was eventually decided to make an independent trip later to the Pacific coast, and to spend some time looking up friends of Engineering News, and in looking up work in the "far west" that would be of interest to its readers.

Erie Railway.

The first stage of the trip was made on the Chicago Vestibule Limited express of the Erie Ry., leaving New York at 2 p. m., on June 30, and one of the first points calling for comment was the apparently small percentage which this route receives of the heavy through traffic between New York and Chicago, meaning thereby the first-class traffic on the express trains more especially. The time is convenient (the Vestibule Limited leaving New York at 2 p. m., and arriving at Chicago at 5 p. m. the next day), and, as was explained in an editorial on "Accelerating the Speed of Express Trains" (Eng. News, Sept. 19, 1895), convenience of time in train service is a greater aid to the encouragement of traffic than is a mere matter of actual speed, or a little saving in time, though as far as this is concerned the speed on the Erie Ry. is practically equal to that of its competing lines. The road is well built and well managed; it is operated on the block system for the entire distance of 998 miles (which at present includes a considerable stretch of single track); the equipment cannot be surpassed by that of any other road in point of comfort, convenience and ease of riding; and the attendance and service on the cars is all that could be desired, while besides all this there is an abundance of fine scenery along a large part of the line. In spite of all these advantages, however, the number of passengers on the through cars has been found on more than one occasion to be comparatively small, which is an additional point of convenience to the passengers themselves, but is not a source of satisfaction to the railway company. Perhaps one reason for this is the unfavorable reputation which the railway acquired in years past, and which still exists as a difficulty which the present management has to contend with in its endeavors to increase the patronage, in spite of which the management has had and is having considerable success in building up its traffic. It is earnestly to be hoped that the many financial troubles of this important system may have been practically terminated by the recent reorganization, and, as has already been noted, there are now but few objections to be made from a passenger's point of view. As to the general aggregate of the through traffic it appears from official information that this line is at least holding its own.

The construction, track and equipment of this road have been described at various times in Engineering News, more especially in the issues of Feb. 8, 1894, and Jan. 9, 1896, and these matters need not therefore be dealt with here. Reference may, however, be made to the excellent standard of maintenance and discipline generally observed. New ballast is being put in quite extensively, but some parts of the western divisions are still very dusty, and an extension of the use of stone and slag ballast as means will permit, will add considerably to the comfort of passengers. The Chicago & Erie Division is being largely relaid with 80-lb. rails, having suspended, broken joints, spliced with six-bolt angle bars. Two important improvements in operating, which have recently been put in force, are (1) the making up of freight trains on a tonnage basis (that is to say, by actual weight of train instead of by a fixed number of cars); and (2), giving the freight engines a straight run of 192 miles (from New York to Susquehanna) instead of changing engines at Port Jervis and thus making two runs of 88 and 104 miles. The advantages and economies resulting from these improvements were editorially commented upon in Engineering News of July 23, 1896. The Chicago Limited express on the particular date of this trip (June 30) consisted of a powerful ten-wheel engine of the class now largely used for fast and heavy passenger trains, a mail car, baggage and smoking car, day car, Chicago sleeping car, Cleveland sleeping car and Cincinnati sleeping car, this latter having a drawing room and a roomy observation platform fitted with camp stools.



THE GREAT HOISTING ENGINES FOR THE ANACONDA COPPER MINING CO.
Union Iron Works, San Francisco, Cal., Builders.

One point which seems to call for criticism in this train service is the method of handling the dining car service. Formerly the dining car on this train was run through for the entire distance, but now dinner is served on a dining car which runs through from New York to Susquehanna, and breakfast is served on a dining car put on at Kent (6.50 a. m.) and taken off at Marion (10.15 a. m.), while lunch has to be scrambled for in an ordinary eating house at Huntington during a stop of only ten minutes, which is a very inconvenient and unpleasant arrangement, especially in bad weather. Of course a through dining car means hauling an extra dead load for many hours, but it ought to be practicable to extend the run of the dining car to include lunch time, or at least to furnish a buffet lunch, as a lunch stop is certainly beneath the dignity of a "Chicago Limited." It is said that when the cars were run beyond Marion to serve lunch the patronage was so light that they were taken off to save the 254 miles extra mileage and the loss on the meals, but it is difficult to see why this should be, especially if the ten minutes stop at Huntington was reduced to an ordinary stop, since no passenger having breakfast before 9 a. m. would want to go without any meal until after 5 p. m.

Dining Car Service.

In the operation of through trains on very long distances an important point for consideration is the best method of arranging the dining car or eating accommodation so as to most satisfactorily meet the comfort and convenience of the passengers as well as the operating requirements. The three principal methods are as follows: (1) To run a dining car right through with the train; (2) To attach a dining car every morning and cut it off at night; and (3) To provide a buffet car service. The first method is undoubtedly the best as far as the convenience of the passengers is concerned, and it insures a supply of provisions in case the train is delayed or the line is blocked, but on the other hand, it involves the hauling of a considerable extra dead load which may be a serious objection on lines having heavy mountain grades. This plan is, nevertheless, adopted by the Northern Pacific R. R. for all its transcontinental trains, between St. Paul, Minn., and Portland, Ore., 2,056 miles. The second method is almost as good as the first, under all ordinary conditions, provided that the car is put on sufficiently early and not taken off too soon, although it often happens that the schedule cannot well be arranged to make this fit in conveniently with the time of arrival at divisional points between which the cars run. Should the train be late, however, in the morning, the absence of breakfast will cause considerable grumbling, while in case of a block or a breakdown the lack of provisions may be very inconvenient. This method is employed by the Canadian Pacific Ry. for its transcontinental trains, at least east of the Rocky Mountains, and in one particular case on that road an accident in winter blocked the track and the Pacific express, minus a dining car, was held for a day or more on the track amid the snowdrifts. Through the Rocky Mountains no dining cars are used, on account of the heavy grades on the line, but the trains are timed to reach the company's hotels at meal times, and it must be said that a very exceptionally good service is maintained at these places, far superior in fact to any other railway eating house at which it has ever been my fortune to take a meal. The meals are excellent, and well and promptly served, but without the slightest hurry or bustle. The amount and character of the traffic, as well as the character of the line, must, of course, be taken into consideration in deciding which of these methods should be adopted in any particular case. In any case it is important to have the meals served at convenient hours, but this is not always done, as for instance, on one part of the run of the eastbound trains on the Canadian Pacific Ry., where breakfast is served at 8.30 a. m., lunch at 11.30 a. m., and dinner at 5.30 p. m. The first interval is too short, and the time for dinner is too early, especially as the car is run until 7.45 p. m. The buffet car service is not adapted for very long runs, but is specially convenient for day runs (serving two or three meals) or night runs (serving supper and breakfast) of 10 to 14 hours' duration. It is also very convenient in cases where single through cars are run, being attached to different trains on the different lines forming the route. In the buffet car, as is well known, the car porter cooks and serves light meals in the car, the charges being a-la-carte, while on the dining car there is usually a fixed price of 75 cts. or $1 per meal, though some roads (including the Union Pacific Ry.) serve meals a-la-carte on the dining cars. For first-class traffic it is not enough to stop the train for 10, 20 or 30 minutes at an ordinary railway eating house, as the hurry and scramble and the character of the food do not suit persons in delicate health or with weak stomachs. This plan is, however, followed on some lines, but while the patronage may not be enough to warrant a dining car service it would in most cases warrant introducing a buffet service on the sleeping or parlor cars. The dining car service is usually operated by the Pullman or Wagner palace car company, under contract, and at a loss to the railway company, but in some cases the railway company could operate this service more profitably, and the Baltimore & Ohio R. R. has recently purchased the dining cars of the Blue Line express trains between New York and Washington, and will operate them under its own management, as they have hitherto been operated by the Pullman Palace Car Co. at a loss to the railway company. It is a common practice to run dining cars on express trains running distances of 100 to 400 miles, as between New York and Philadelphia, Boston or Buffalo. The Lehigh Valley R. R. has also a unique lunch car service on excursion and day trains, the car being fitted with a regular lunch counter where light refreshments are served.

Chicago.

This city was reached at 5 p. m., July 1, and was left again at 6 p. m., on July 2, only one day being spent here, as all engineering matters of interest in that vicinity are well looked after by the Chicago editor of Engineering News, and it was a relief to get away from the heat and humidity of that city.

One of the striking pieces of engineering work now in progress is the lowering of the grade of the Illinois Central R. R. along the lake front, and the reclamation of submerged land to form a park east of the railway. Practically the whole of the lake front, for a long distance south from the mouth of the Chicago River has been occupied by the railway, but now there is to be eventually a fine lake front park close to the main business part of the city, similar to Lincoln Park and Jackson Park in the north and south suburban districts of the city. A bulkhead or sea wall, 6,200 ft. long, is now being built 1,250 ft. from the shore, and the space between this and the present shore will be filled in, forming a park of some 164 acres, the grade of which will be sufficiently high above the railway to allow of bridges spanning the tracks. The filling in, on such a large scale, will be quite an interesting piece of work in itself.

Another noticeable work is the construction of the terminal loop for the joint use of the several elevated railways, and while this will be a great advantage to the local traveling public, it must be said that the structure is very detrimental to the appearance of Van Buren St. This work was described in Engineering News of July 16 and Aug. 20, 1896. The demolition of the old Post Office, to make way for a new structure (with presumably better foundations) on the same site, is an indication of progress. The noted Grand Pacific Hotel, opposite the Post Office, is closed and is to be pulled down, while on its site a trust company intends to erect a one-story business building for its own sole use and occupancy, the idea being to follow somewhat the plan of the Bank of England (in London). Thus Chicago, which first began the craze for sky-scraping buildings of 15 to 20 stories (and which has now been surpassed in this respect by New York), has now gone to the opposite extreme, and will have a lowly (though by no means a humble) one-story structure in that section of the city where 12 to 15-story buildings are quite common. There is no indication, however, of any cessation of the construction of tall buildings. At Lincoln Park may be seen the great 250 ft. Ferris wheel from the Columbian Exhibition, and the taking down and re-erection of this wheel must have been a complicated and troublesome work. It is now in a small private park, operated by a syndicate, but as this syndicate has not been able to secure a liquor license, it does not seem likely that the park and wheel will be a popular resort or a profitable enterprise. One must not leave Chicago without a reference to its Drainage Canal. The main work of the canal proper is now practically completed, and its extension to the lake is now being advocated by those who look upon the drainage channel as a part of an important navigable canal to connect Lake Michigan with the Mississippi River.

Chicago & Northwestern Ry.

The Wells St. terminal station of this road is not very large or imposing, but the long through trains which one sees in the station, with cars labeled for various far away cities, give an impression of the great extent of the railway system and its direct connections. It may be noted in passing that this is one of the few American stations at which a service of porters has been established, but while these red-capped assistants are conspicuous enough they are not very alert or attentive, and are in no way to be compared with the prompt, active and obliging (albeit somewhat obsequious) porters who abound at all the English terminal stations. The same remarks apply to all the station porter services in this country, which have come under my notice, including those at the Grand Central Station, New York, and the Union Station, at Boston.

The route of the Overland Limited express for the Pacific coast is by way of the Chicago & Northwestern Ry. to Omaha, the Union Pacific Ry. to Ogden (through Cheyenne), and the Southern Pacific Ry. to San Francisco. This train leaves Chicago at 6 p. m., and is due at San Francisco, 2,357 miles, at 8.45 p. m., the second day, or in 74¾ hours. On July 2 this train consisted of eight cars, as follows: Union Pacific Ry. baggage and smoking car, Pullman sleeping car for San Francisco, three Wagner sleeping cars for Salt Lake City, Hawarden and Sioux City, a through dining car for San Francisco (on which meals are served a-la-carte), a Union Pacific Ry. reclining chair car for Ogden and a Chicago & Northwestern Ry. day car in the rear. The locomotive was the powerful eight-wheel engine, No. 908, illustrated in Engineering News of Jan. 9, 1896, which was one of several built by the Schenectady Locomotive Works, of Schenectady, N. Y., and designed specially for high speed with heavy trains between Chicago and Omaha, 492 miles. These trains have from 8 to 11 cars, with sometimes as many as 6 sleepers. The engine has cylinders 19 × 24 ins., driving wheels of 6 ft. 3 ins. diameter, and weighs 125,600 lbs., with 78,000 lbs. on the driving wheels. Its appearance is somewhat grim, being painted entirely black, relieved only by the glistening of the varnish and the bright finished edges of the coupling rods, which are of I-section.

In leaving Chicago the great amount of work for the elevation of the tracks above the street grade (Engineering News, Aug. 20, 1896) is very noticeable, as is also the extensive use of the Hall automatic block signals. During the night a furious and long continued thunderstorm on the plains necessitated the slowing down of the train on account of fear of washouts, the torrents of rain obstructing the view almost like a solid wall of water, while the vivid and almost incessant flashes of lightning blinded the eyes. This road has a very good and easy riding track, and on double track divisions the trains run on the left hand track, which is contrary to the general custom.

Omaha, Neb.

This city was reached at 8.10 a. m., July 3. The train makes a stop of some 15 minutes at Council Bluffs, Ia., on the east side of the Missouri River (which is not a very imposing stream at this point) and in the yards the train has its running gear inspected and the tanks of the cars supplied with water and ice. After this it crosses the river and enters the city of Omaha, which is noted as the starting point of the Union Pacific Ry. (for the first transcontinental line) in 1865. The city has a population of about 150,000, and is 1,031 ft. above sea level.

Leaving the train to proceed on its way, a few hours were spent here, but the heat and humidity made a combination unfavorable to much sightseeing. Here, as in most of the large western cities, one cannot but be struck with the number of large and handsome office buildings, many of them owned by insurance and trust companies. The main part, or business section of the city, is of good appearance, but everything appeared to be very quiet, with little business in progress, times being dull now all over the country. The city has suffered somewhat from a land boom of some years ago, when prices became inflated and everybody was buying and selling land, but this boom died out or collapsed, as booms do, and left more or less injurious effects behind. However, the city is an important railway and commercial center and has some manufactories, distilleries, smelting works, linseed oil works and large meat packing establishments, ranking the third city in the country in this latter respect. The general offices and the extensive shops of the Union Pacific Ry. are also located here. A Trans-Mississippi Exhibition is to be held in Omaha, from June 1 to Nov. 1, 1898, and is intended to be an exhibition illustrative of the resources, products and possibilities of the western regions, and designed particularly to educate people in the east and south as to these matters. This was decided upon in 1895 at the eighth convention of the Trans-Mississippi Commercial Congress, and the matter has been energetically pushed, while the U. S. Congress has appropriated $200,000 towards the expenses of the exhibition. Mr. G. W. Wattles is President of the exhibition, and Mr. C. F. Weller is President of the Omaha Commercial Club.

The union station is at some distance from the business section of the city, and is an old, shabby, one-story frame structure at the side of the track, having been built apparently in the early days of the Union Pacific Ry. It has no trainshed, no modern conveniences, and only a very third rate dining-room and lunch counter. Some time ago the Union Station Co., in which the Union Pacific Ry. is interested, received authority and assistance from the city to build a new station close to the old one, but on the opposite side of the tracks, the city voting bonds to assist the project. Work was commenced and the lower part of the building practically completed, when the city made objection that the plans submitted by the company were not being strictly adhered to, but that certain dimensions had been reduced. The repudiation of the bonds was threatened, and this led the company to stop work and the railways to abandon the project. The partly completed building (which appears to have been designed as a handsome and commodious structure of brick, stone and iron), remains a weatherbeaten monument to the difficulty of ensuring harmonious relations between railway and municipal authorities. A project now on foot is to build a new station on a different site, more nearly within the city, and accommodating some other roads. This station would be a terminal having a headhouse, which does not seem to be the most desirable plan for a station which has to accommodate so much through traffic, as was noted in Engineering News of July 16. Wherever the new station may be located it should certainly have a trainshed, as no amount of splendor or comfort in the station building can compensate for the inconvenience and discomfort of passing between station and train during rain and snow. Yet it must be said that this is a common defect of many new and handsome stations, not even the makeshift of a shed roof over the platforms or between the tracks being provided.

(To be continued.)

THE REQUIREMENTS OF TIE-PLATES FOR RAILWAY TRACK.

By Benjamin Wolhaupter.

As soon as George Stephenson triumphed with his locomotive "Rocket," in 1829, he became the recognized authority in railway construction, and he adopted the fish-bellied rail with chair supports, which had already been in use for some time. The rail was first laid without chairs, these supports having first been used about 1797. The use of such chair supports has been continued in service in England on all up to the present day, but with the bull-head rail. In America they were soon discarded, the Stevens flange or T-rail being adopted, made with a flat base and spiked directly to the ties, and the chairs placed only at the joints. Under these conditions the chairs were subjected to a heavy rocking and pounding action by the passage of the train over the light iron rails then used, which soon battered out the joint ties and the rail ends. These joint chairs have long ago been obsolete, having given place to the more scientific fish plate joint. On account of the great weight and the looseness of the joint chairs, and the alternate loading on one side and then the other, and the hammer blows before mentioned, they destroyed the joint tie rapidly, and have remained up to the present time in much disfavor with old engineers who once used them. Hence it was that the first tie-plates were received with much skepticism by engineers, and it is even now not fully recognized that the tie-plate is distinct from a chair. Much credit is due to Mr. Benj. Reece for the manner in which he has carried out his practical tests with tie-plates, and educated the engineering world away from the false impressions formerly existing regarding them.

The tie-plates are placed directly upon wooden ties, and we find that all wood is composed of a fibrous, cellular or minute tubular structure. This is of two kinds in the same wood; one kind practically open, thin-shelled tubes called "ducts," which when new are filled with sap, and when old, filled with air. The other is of a hard dense, thick-shelled nature, and is called the "woody fiber," and is the "substance" of the material, and it is through these cells that the sap flows. It is thus evident, that to entirely exclude moisture and air it is necessary to compress the walls of these tubes together and keep them so compressed. In "soft woods" the shells or walls of these "woody fiber" tubes are thin, and consequently allow of great compression. In "hard woods," on the other hand, they are thick and strong, and leave little room for the sap to ascend through them. Therefore, a certain definite pressure applied to the former will compress them (squeezing out the air and moisture) to a greater extent than it will in the latter.

The prime requisite of all "base" of track below the rail head, whether of rail, plates, ties, or ballast, is to carry the loads received from the wheel treads and equally distribute them to the roadbed (which is the final supporting medium) in such a manner that no single part shall receive, and be required to transmit, a strain beyond the elastic or crushing limit of its component particles. Where this is not carefully guarded against, rapid deterioration takes place and soon complete destruction.

Except during the coldest weather in the northern section of this country, all ballast is flexible and forms a yielding support to the track. The rail also is flexible and will bend and spring within the elastic limits of the steel of which it is composed. Therefore, when a heavily loaded wheel passes over the track, depression of the rail immediately below the wheel takes place, the adjacent ties supporting the rail will force it into a curve, thus tending to raise it off the second ties from the wheel, to be instantly forced onto the tie as the wheel reaches it. Thus is produced a certain undulatory or wave motion in the track, which may cause the rocking or churning of the tie as the wheel passes over it, a rise and fall of the rail on the tie, and also a longitudional movement of the rail bodily. We will call these the first forces acting on the tie-plate, and will call them longitudinal and rocking forces. Under excessive loads, light rail and poor ballast, these conditions are magnified.

Fig. 1 shows tie plates in use with the above conditions of forces on an exaggerated scale. It will be seen that the tie-plate will first receive a blow and then a heavy load on one edge, forcing this edge into the tie, compression of the fiber under this edge takes place, lifting the other edge off the tie. Next the middle of the tie is loaded centrally, and finally the opposite edge of the plate is loaded, forced into the tie, lifting the other edge of the plate off the tie, the tie moving in the ballast to correspond slowly with the action as above. This action will increase with the width of the plate and the softness of the tie. It is similar, also, but in a minor degree, to the action of the load on the old joint "chairs" in use on iron rails, and would in time cause the destruction of the tie, unless the plate is immovably fixed thereon. This deleterious action can be entirely overcome by giving a central point of support on the plate as shown in Fig. 2, or by making the plate sufficiently narrow. Some well-known plates have been made 6 and even 10 ins. wide, with a smooth top surface, but experience has shown that they would rock on the tie, become loose, and soon grind out.

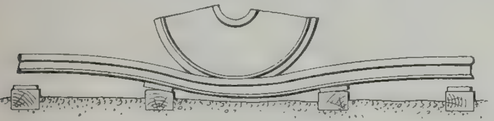


Fig. 1.

One of the most detrimental actions of track in practice is the rise and fall of the rail on a flat plate. With high speed the rail is raised instantly off the plate on which a close contact had been previously maintained. At once air rushes in with excessive velocity, carrying with it sand and other gritty particles. This sand grinds between the rail and the plate, and as is perfectly clear on examination of an old plate, wears a thin plate through in a short period. The larger the rail base and the plate, the greater the velocity of the air and the greater the tendency to suck in grit. This grinding of the sand on the plate is one of the chief sources of destruction of tie-plates in practice.

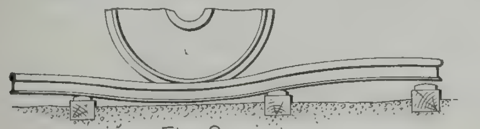

Fig. 2.

The second and greatest loading on the plate is the vertical loading, produced by the wheel and its superincumbent load applied to the rail head, and through it and its base direct to the tie-plate. Referring now to Fig. 3. This vertical force is applied to the rail head at G, and is then transmitted vertically through the rail web to F, where the web joins the base A B. Here the tie-plate takes it and is called upon to distribute it over the tie and out to its outer edges at C and D, and in doing so must not have its fibers strained beyond their elastic limit. If they are so strained, the plate will buckle or curl up at the edges of the rail flanges, because there the greatest bending moment occurs, and the plate will assume the shape shown in Fig. 4. It will then become loose and rattle; will suck moisture beneath it and will apply a hammer blow to the fibers of the tie as the wheels pass over it.

There are three methods of preventing this bending of plates: (1) increasing their thickness; (2) decreasing their length; or (3) adding vertical ribs or "girders" from end to end of the plate. If the first method is resorted to, the plate becomes too heavy for economical practice, and at the same time from its inertia cannot be immovably secured to the tie. By the second method the area of bearing on the tie is greatly reduced. By the third method the objections to the two former are answered, and the exceedingly important feature of providing successful means for securing the plate to the tie is obtained by opening up the grain of the wood and placing the flanges therein.

Considering the plate strong enough for this purpose, it is next the duty of the fiber of that part of the tie immediately beneath the plate, namely D, H, K, C, Fig. 3, to support this distributed load without being crushed or torn away from the adjacent fibers at M and N. From the spaces beneath the plates this force is distributed through the tie to the ballast beneath.

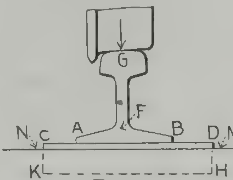

Fig. 3.

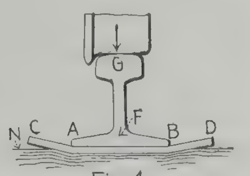

Fig. 4.

For the simplification of this question of the vertical force, let us assume that each tie supports its own section of rail and is called upon to individually carry the load coming to that section. The loads we find as follows:

Locomotives (Central R. R. of New Jersey), 88,400 lbs. on 4 drivers; 22,100 lbs. on 1 driver.

Modern box car (light weight), 32,000 lbs.; full load, 60,000 lbs.; 92,000 lbs. on 8 wheels, 11,500 lbs. on 1 wheel.

Considering now the effect of these loads upon the two extreme cases of cedar and oak ties we find that with a 60-lb. rail having a base 4¼ ins. wide, resting on a standard tie 6 × 8 ins., the area of contact will be 4¼ × 8 ins., or 34 sq. ins., on which a load of 22,100 lbs. will give 650 lbs. per sq. in. The effect of this load passing over at high speed and thus being suddenly applied should be considered as double this, or 1,300 lbs. per sq. in. The wood of ties used varies in different sections of the country, and includes soft white cedar, cypress, redwood, chestnut, pine and hard oak. Considering the compressibility of the tie, we find that the extensive U. S. government tests of the compressibility of woods at Watertown, Mass., show that 0.1-in. of indentation is made on unseasoned cedar with a load of 450 lbs. per sq. in.; on thoroughly seasoned cedar, 900 lbs. per sq. in.; on unseasoned white oak, 2,000 lbs. per sq. in.; and on seasoned white oak, 4,000 lbs. per sq. in. The pressures on other woods to give a like indentation varies between these two extremes in the proportion of the hardness of their fibers. It is thus clear that with a perfectly vertical application only of the above loadings it is only in the softer woods when moist that the fibers will crush and destroy the life of the tie.

The above examples are of extreme conditions of the present practice as to loading, conditions of wood and width of rail base, and hence it would appear that under favorable conditions no additional bearing surface in the form of a tie-plate would be required in addition to the ordinary rail base, even on soft ties, to take care of this vertical load.

The third loading or strain applied to tie-plates is apparently insignificant except upon the sharpest curves. It is a lateral force and is caused on curves by the centrifugal force produced by the load moving around the curve. It is applied to the rail head by the wheel flange and is carried through the web to the base and there applied to the tie-plate and spikes, and through them to the tie. On tangents this force is produced by the swaying of the train, side winds, unlevel track and trucks skewed out of square, and though apparently comparatively slight, produces with the other before mentioned forces, the chief source of tie and tie-plate destruction.

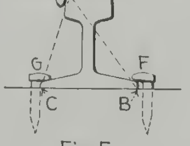

Fig. 5.

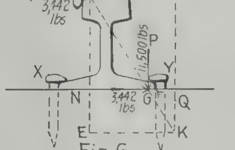

Fig. 6.

Referring now to Fig. 5 and considering that this lateral force is applied at the head of the rail at D in the direction A D we see that it thus tends to move or slide the rail laterally on its base B C until it comes in contact with the spike F, after which the tendency is for the rail to revolve on its edge B, elevating the other edge C and drawing spike G. This latter action is prevented by the vertical load from the wheel. In fact it is necessary to consider both of these forces together. Considering now both of these forces together and applying them as produced by the car before mentioned, we get the forces shown in Fig. 6 (where spikes G and F are marked X and Y respectively).

By assuming an extreme case of speed of 40 miles an hour around an 8° curve and using the formula:

$$f = \frac{w\,v^2}{32.166\,R}$$

(Searles' "Engineers' Pocket Book," p. 177) for the centrifugal force, where f = centrifugal force, w = weight of car in pounds, v = velocity of car in feet per second, and R = radius of the curve in feet. In this case w, on one axle, is 23,000 lbs.; v is 40 miles per hour, or 58.67 ft. per second; R is an 8° curve, 716.8 ft. radius, thus giving us a horizontal force, f, of 3,442 lbs. We have already a vertical force of 11,500 lbs. applied to point A. Forming now the parallelogram of forces A D K E we find a resulting force acting in the direction A K and striking the rail base at G, where it is again resolved into the original forces of 3,442 lbs., acting along the base of the rail in line N G and 11,500 lbs. acting vertically in line P G. In an 80-lb. rail G comes within ⅜-in. of the edge of the base.

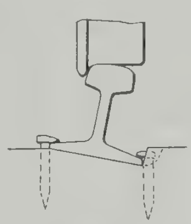

Fig. 7.

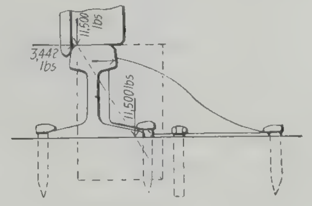

Fig. 9.

We have now the most serious and extreme condition in which ties and plates are placed, and under which ties will cut, and improperly designed tie-plates will fail. Assuming that this 11,500 lbs. of vertical force applied at ⅜-in. from the edge of the rail is distributed over 8 ins. of tie for a width of ¾-in., we now get a loading on fibers of 11,500 lbs. divided by 6, or 1,917 lbs. per sq. in. This pressure will cause a very decided compression of the fibers of all of our tie woods and even of the hardest oak along the edge of the rail at Q, as before shown, and as the wood gets old this will soon cause destruction. At the opposite edge but little pressure exists.

It has just been shown, however, that except under the extreme conditions found in practice a purely vertical force will not destroy a soft wood tie. We now find that under ordinary conditions with a lateral force added to the vertical, we get a destructive force even for the hardest oak. Further we have a horizontal force which moves the rail until it comes in contact with spike F (or Y) under this extreme vertical pressure. These two combine to rapidly destroy the fibers even of the hardest wood on this side, and as they give way the rail cants, thus throwing the resulting forces nearer the edge of the rail flange, which soon throws the rail into the position shown in Fig. 7.

This concentrated vertical pressure and the lateral pressure causing movement of the rail, combined with the destructive abrasive action of the sand on the wood fibers beneath, is the chief source of tie-plate wear, and can be avoided only by a carefully designed plate. The plate, however, must be fast to, or embed itself in the tie, otherwise there will be movement between plate and tie which will also cause absorption of moisture and sand, severe abrading action and complete destruction of the tie. The eccentric loading, however, not being so great as with a rail alone, it will take a greater period of time to cause such destruction.

This before-mentioned lateral pressure and its resulting action are the cause of the chief differences of opinion among the advocates of the two types of tie-plates.

Considering now the resistances encountered by this force from the base of the rail until it is absorbed in the tie, we find that this lateral pressure is absorbed (1) by the friction of the rail on the tie or plate, and (2) by the resisting action of the spike. As the tie becomes smooth, the co-efficient of friction will amount to 0.18 (Trautwine's "Engineers' Pocket Book," p. 373, steel, on smooth mahogany) or 2,070 lbs., leaving 1,372 lbs. to be resisted by the spike. Allowing now the very low shearing strain of 30,000 lbs. for iron used in spikes, we have for a spike 9-16 × 9-16-in. square, 0.316 sq. in. of area, or 9,490 lbs. of shearing strain to resist a thrust of 1,372 lbs.

Though the spike will not shear under these conditions it is supported by wood which may compress and give way. Assume that for 2 ins. down the spike the fibers of wood are compressed, and we have 9-16 × 2 ins., or 1,125 sq. ins., or say 1,220 lbs. per sq. in. on the fiber produced by the 1,372 lbs. of thrust. If there is any material rail movement before the rail strikes the spike and a blow is given, this should be doubled, or say 2,440 lbs. The resisting power, however, of the end of the fibers amounts to from 4,400 lbs. per sq. in. in cedar to 7,000 lbs. per sq. in. in oak. On a bare cedar tie we thus have a factor of safety of 2.

If a tie-plate is used under the above conditions, we have a co-efficient of friction of 0.14, or 1,610 lbs. of friction on the plate, leaving 1,732 lbs. to be resisted by two spikes, and if the plate is punched, as it should be, in such a manner that no rail movement is allowed between the spikes, we thus obtain with a tie-plate a factor of safety of nearly 6 under these conditions with cedar. This factor of safety certainly should be all that is required.

In the above examples, forces and conditions were considered which can be readily ascertained. In practice, however, these conditions will vary, and when varying can never be accurately obtained. They may be varied for such reasons as the following: Short sections of track may have very narrow rail base, gage of track may be tight, locomotives may have long, stiff wheel base and frames, ties may be old, besides which spikes when driven are not entirely supported by the end wood but partly by end wood and partly by side wood.

The conditions of these forces, as has been shown, require a narrow plate or one with a raised center; they also require one which will collect little or no sand. The Wolhaupter plate (Eng. News, July 18, 1895, is only 4¼ ins. wide, and can be made with a raised or crowning center, under special patents. It also has channels on top, thus allowing large air ducts beneath the rail, which greatly reduce the velocity of the inrush of air and at the same time afford channels for collecting grit or sand that may get beneath the rail base. In practice this is very noticeable.

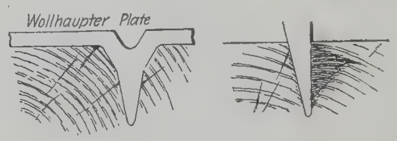

Fig. 8.

The vertical force was shown to amount to 650 lbs. per sq. in. on an area of 4¼ × 8 ins., which is also the size of this style of plate. This loading on a cedar tie was not injurious, and as the plate has bottom flanges it carries this loading right to its extreme ends without buckling. The lateral force combined with the vertical has been shown to move the rail on the tie under a large vertical load and to rapidly disintegrate the wood fiber thereby and to be the chief source of tie destruction. The Wolhaupter tie-plate has flanges which embed themselves parallel with the grain of the wood and is therefore held firmly by such flanges, it being a well-known fact that the expansibility of wood is almost entirely at right angles to its fibers. In a heavy terminal yard with excessive traffic, where the Wolhaupter plate, a plate of the same type and one of a type having flanges cutting across the fibers were placed, the former plate was in for ten months; the others for seven months each. The plates having flanges across the grain had 1% tight at the end of the seven months; the plate of the same type as the Wolhaupter had 16.7% tight at the end of seven months; the Wolhaupter plate had 34.5% at the end of ten months.

A great source of tie destruction, in addition to the action of the forces above mentioned, is the natural decay of the wood. This decay is caused by the alternate absorption and evaporation of water, which action a flat or loose plate will of course increase. The flanges of the Wolhaupter plate being V-shaped on top, compress the upper fibers of the wood to such an extent as to tend to prevent absorption of moisture. Careful examination will show that if chisel-pointed flanges are driven into soft wood parallel with its grain, the top surface of the wood is readily penetrated by the flanges. The fiber immediately beneath is, however, carried down with the flanges, and thus forms a pocket or receptacle for moisture immediately beneath the surface of the tie and next to the flange of the plate as shown in Fig. 8. The plate having these V's at the upper end of the flanges compresses the surface fiber down into these cavities, filling them and preventing the collection of moisture at these points.

A slight consideration of the strains placed upon tie-plates and rail braces will show readily which of them must of necessity be the preferable.

In Fig. 9 we have a rail brace, and (as before illustrated in Fig. 5) vertical and lateral forces produced by a loaded car on a curve. We see that here the only force which the rail brace is capable of resisting is the lateral or horizontal one of 3,442 lbs., which is only one quarter of the other or vertical force; in other words, the rail brace is placed to resist this small force, and the greater force of 11,500 lbs. takes care of itself on soft woody fiber. This might be possible if the braces were absolutely tight against the rail head, but in practice this is not so, and the moment looseness occurs between the head of the rail and the braces, we get a concentrated load at G as before; then the tie cuts, the rail cants and carries down with it the head of the brace, at the same time canting up the other end.

On the other hand by using tie-plates this great vertical force of 11,500 lbs. is distributed over the tie. The small lateral force of 3,442 lbs. is readily taken care of by the friction of the rail on the plate, but more particularly by one inner and one outer spike, or in extreme cases by two outer and one inner. A number of railways, after making careful comparative tests both of rail braces and tie-plates have had such strong practical demonstration of the above facts that they have abandoned the former and adopted the latter.

VERTICAL LIFT LOCK FOR DORTMUND AND EMS CANAL, HEINRICHENBURG, GERMANY.

(With inset.)

A vertical lift lock, possessing several novel features in its construction, has been built to overcome a rise of 16 m. (62.48 ft.) at Heinrichenburg, on the Dortmund branch of the new canal, being constructed to join the Rhine and Ems Rivers in Germany. Except in the height of lift this lock corresponds very closely in size to the proposed lift lock for the Erie Canal at Lockport, N. Y., and in view of the full description of the Lockport structure given in Engineering News, April 18, 1895, it is interesting to study the ideas of foreign engineers in the solution of their very similar problem. As a preface to this consideration it may be stated that in the issue of Engineering News, noted above, the structural features characteristic of this type of canal locks were described and their advantages and disadvantages under different conditions were discussed at length. For the description of the Heinrichenburg lock given here we are indebted to an article in our French contemporary "Le Genie Civil."

The construction and operation of the Heinrichenburg lift lock are indicated in a general way by Figs. 1, 2 and 3. As will be seen, a trough or lock chamber of sheet iron, 70 × 8.6 × 2.5 m. (229.6 × 28.2 × 8.2 ft.) is carried on five hollow cylinders immersed in vertical wells filled with water. The buoyancy of these cylinders when midway of the total rise, 16 m., just counterbalances the superimposed load, which comprises the weight of the cylinders, the metal work of the trough and supporting framework, and the water in the trough. Any increase or decrease, therefore, in the superimposed load tends to cause a vertical movement of the cylinders and lock chamber. To quiet this movement four framework towers of steel are located about at the four corners of the lock chamber, and to regulate the movement as well as to supply the additional force necessary to cause it under certain conditions, four screws are placed, one at each tower.

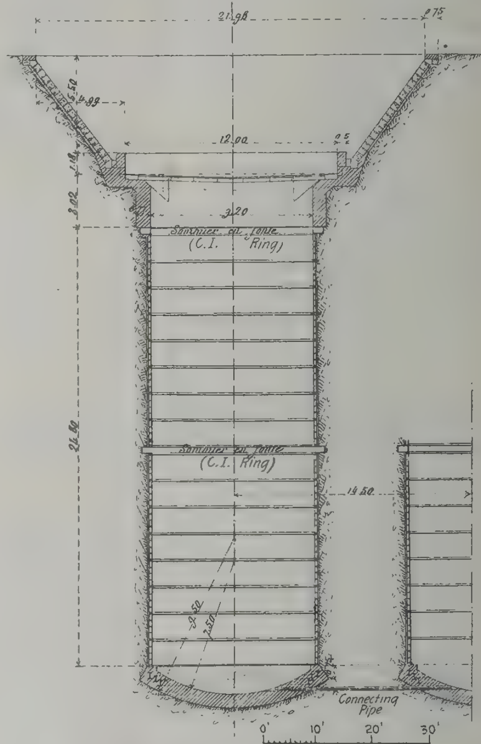

Fig. 5.—Cross Section of Well.

The mode of operation is evident from the foregoing. When it is wished to pass a vessel into the lock the gate of the lock chamber and that of the corresponding level of the canal are opened. The vessel once being in the lock the gates are closed and the lock chamber raised or lowered, as may be desired, to the opposite canal level. The process of taking the vessel from the lock chamber is similar to that of passing it into the lock chamber. Power for operating the lifting screws, the lock and canal gates, and the capstans hauling the boats, is furnished by a 220-HP. electric plant. With this general explanation attention may now be turned to the details of construction.

In constructing the lock the first work was the excavation of the pit and the construction of the wells. The excavation was on a side hill, but the material was very favorable, being a marl, with occasional seams of rock, but bearing very little water. The surface dimensions of the excavation were 100 × 54.5 m. (328 × 178.76 ft.), which, with the slopes and terrace, Fig. 4, gave 72 × 11.5 m. (235.2 × 37.7 ft.) as the bottom dimensions of a pit 12 m. (39.36 ft.) deep. The five wells were begun at this bottom level. These wells are 9.2 m. (30.17 ft.) in diameter, each, and were placed 11.5 m. (37.7 ft.) apart, c. to c., in a single row. At the top of each well a ring or crown of concrete was built and at the bottom there was placed an inverted dome or spherical segment of the same material. The sides of the wells were lined with cast-iron rings or cylinders, each 1.5 m. (4.92 ft.) deep. These consecutive rings were screwed together, the hub and spigot ends being threaded for this purpose, and made tight by lead joints. The well construction is clearly shown by Fig. 5, and the nature of the plant used in doing the work is shown by Fig. 4. Altogether seven months were required to complete the excavation and well con-

struction, exclusive of the construction of the passageways connecting the bottoms of the wells. The work was done by the contractors for the lock, Haniel & Lueg, of Dusseldorf, Germany.

Following the well construction, work was begun on the foundations for the operating screws. Four rectangular wells 2 × 2.6 m. (6.56 × 8.52 ft.) in lateral dimensions and 10 m. (32.8 ft.) deep were dug and a pier of concrete built at the bottom of each. These piers take the thrust of the screws, which, under certain conditions, amounts to 1,600 tonnes. Simultaneously with the construction of the screw foundations, work was completed on the towers, the nature of whose construction is shown by the illustrations. Each screw was a single piece of forged steel 24.5 m. (80.36 ft.) long, 17.5 m. (24.6 ft.) of which are threaded, and has an outside diameter of 28 cm. (11 ins.). To make certain of the quality of the material a 100 mm. (3.93 ins.) hole was bored the entire length of each screw at the center.

The floating cylinders were built by the Harkort Works, of Duisburg, Germany. Each was 8.3 m. (27.22 ft.) in diameter and 10.275 m. (33.7 ft.) long, outside dimensions, and had cylindrical sides and spherical ends. The material was 18 to 20 mm. (0.7 in. to 0.78 in.) steel plates. Inside each cylinder was a steel framework to give rigidity to the surface plates. Each cylinder carries a tower of steel framework and the tops of all five towers are connected by a bridge which carries the iron trough or lock chamber and gives it the necessary bracing. The trough itself is made of 10 mm. to 14 mm. (0.39 in. to 0.55 in.) iron plates, which are reinforced on the bottom with plates varying in thickness from 8 mm. (0.31 in.) at the center to 16 mm. (0.62 in.) at the sides.

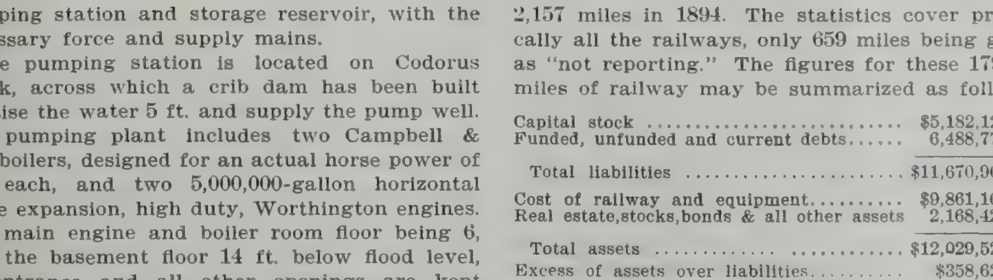
The power for operating the screws is provided by a 150-HP. electric motor located in a cabin at the middle of the bridge connecting the four main towers. From this motor the power is conveyed by the shafts and gears plainly shown by Figs. 1, 2 and 3. The speed of travel given to the lock chamber by this machinery is 10 cm. (3.937 ins.) per second, making the time necessary to pass a boat through the lock 15 minutes altogether. An independent motor of 100-HP. operates the lock gates.

The foregoing description and illustrations give a very fair idea of the Heinrichenburg lift lock. No figures of the cost of construction are available nor is information yet available regarding the success of its operation.

◆

IMPROVEMENT TO THE WATER SUPPLY OF YORK, PA.

One of the earliest towns in the United States to enjoy a public water supply was York, Pa., where works were built in 1816 by the York Water Co. What parts of the old works, if any, are still in use, we cannot say. Just now the works are being improved by the addition of a pumping station and storage reservoir, with the necessary force and supply mains.



SECTION OF RESERVOIR EMBANKMENT, YORK, PA.
Chas. A. Hague, M. Am. Soc. C. E., Engineer.

The pumping station is located on Codorus Creek, across which a crib dam has been built to raise the water 5 ft. and supply the pump well. The pumping plant includes two Campbell & Zell boilers, designed for an actual horse power of 350 each, and two 5,000,000-gallon horizontal triple expansion, high duty, Worthington engines. The main engine and boiler room floor being 6, and the basement floor 14 ft. below flood level, the entrance and all other openings are kept above that level to prevent flooding. There is a gallery floor at the entrance with steps down to the main floor.

The pumps work under a pressure of 150 lbs., delivering water through a 24-in. cast-iron force main, about 11,000 ft. long. This main passes over four hills and at the summit of each is an air vent consisting of a 24 × 8-in. T-branch, surmounted with one length of 8-in. pipe, properly protected at the opening.

The reservoir has a capacity of about 40,000,000 gallons. It is built in two compartments, is located on a hillside, and is formed by a curved embankment somewhat resembling a horse-shoe in shape. A section through the main embankment is shown by the accompanying illustration.

The force main extends over the top of the embankment, instead of through it. There are two gatehouses, one at the adjoining corners of the two basins, arranged so as to draw water at two different levels, from either or both basins. The other gatehouse is at the foot of the outer slope, and controls the supply in either of two directions, or permits the emptying of the reservoir through the one outlet pipe. A new 20-in. supply main will lead to the city. The reservoir has an overflow into a ravine through a culvert.

We are indebted to Mr. Chas. A. Hague, M. Am. Soc. C. E., of 39 Cortlandt St., engineer for the improvements, for the information given. The contractor for the pumping station, reservoir, force and supply mains was Mr. John Berkery, of New York city and West Hoboken, N. J. Mr. J. L. Kuehn is superintendent of the York Water Co.

◆

THE RAILWAYS OF THE UNITED STATES IN 1895.

The introduction to the yearly volume of Poor's "Manual of Railways" always contains a summary of the statistics of the railways for the preceding year, and we give below an abstract of these statistics, taken from advance sheets of this introduction for the volume for 1896, which is the 29th annual number. The statistics are for the year 1895, and the book is issued somewhat later than usual, for which three reasons are given: 1, an increase of 300 pages in size; 2, the delay occasioned by printers quitting work for more than two weeks during the recent hot spell; and 3, a loss of over two weeks on account of a printers' strike. The total mileage of railway on Dec. 31, 1895, was 180,955 miles, only 1,627 miles having been built during the year, as against 2,157 miles in 1894. The statistics cover practically all the railways, only 659 miles being given as "not reporting." The figures for these 179,821 miles of railway may be summarized as follows:

Capital stock	$5,182,121,999
Funded, unfunded and current debts	6,488,779,615
Total liabilities	$11,670,901,614
Cost of railway and equipment	$9,861,102,973
Real estate, stocks, bonds & all other assets	2,168,421,392
Total assets	$12,029,524,365
Excess of assets over liabilities	$358,622,751
Train mileage, passengers	327,294,734
" " freight	491,410,820
" " mixed	15,457,939
Total revenue train mileage	834,163,493

Passengers carried		543,974,263
Passenger, mileage		12,642,202,551
Freight moved, tons		763,799,883
Tons of freight moved one mile		88,567,770,801
Earnings, passenger		$261,640,598
" freight		743,784,451
" other		87,714,556
Total traffic revenue		$1,093,139,605
Operating expenses		$769,943,151
Net earnings		323,196,454
Rentals and other receipts		113,768,075
Total available revenue		$436,964,529
Payments from available revenue:		
Interest on bonds	$239,944,229	
Other interest	8,191,655	
Dividends	81,375,774	
Rentals, tools, etc.	68,885,266	
Miscellaneous	33,404,887	
Total		$431,801,811
Balance		$5,162,718

A comparison with the general results of operation in 1895 and in 1894 are given in the following table, from which it will be seen that the differences are very small, but are encouraging as compared with 1894, for which purpose we have added the last column of the table, showing the percentage of increase and decrease of 1894 over 1893. In 1895 the freight traffic increased 11.72% over 1894, but the earnings from freight only increased 6.18%, while the passenger traffic and earnings show a decrease.

				P. c. of increase or decrease.	
	1895.	1894.	Increase or decrease.	In 1895.	In 1894.
Miles of railway operated	179,162	176,229	+ 2,933	+ 1.66	+ 1.19
Tons of freight moved	763,799,833	674,714,747	+ 89,085,086	+ 11.72	—10.85
Freight mileage	88,567,770,807	82,219,900,498	+ 6,347,870,303	+ 7.72	— 9.12
Passengers carried	543,974,263	583,248,007	— 39,273,744	— 6.73	— 7.25
Passenger mileage	12,642,202,551	13,600,531,635	— 958,329,084	— 7.05	—10.20
Earnings, freight	$743,784,451	$700,477,409	+ 43,307,042	+ 6.18	—13.36

" per ton per mile, cts.	0.839	0.864	+ 0.025	+ 2.89	— 4.70

A statement prepared with a view to ascertaining the relation borne by the great trunk lines of railway to the entire railway system of the country shows that 59 railway systems control more than 61% of all the railways in operation. Of the passengers carried in 1895 (543,974,263) these 59 systems carried 386,625,325, or 71%, a total distance of 9,686,080,240 miles at an average charge of 2.016 cts. per passenger per mile, against a general average of 2.069 cts. for all the railways of the country. Of the freight tonnage they hauled 60%. Their aggregate haulage equalled 67,268,068,380 tons one mile, being 76% of the grand total, while the average charge per ton per mile was 0.834 ct., or 0.015 ct. less than the general average for the whole country.

The street railway statistics may be summarized as follows, but it is stated that many companies have furnished very meager information. The rapid substitution of electric traction for horse power may be gathered from the fact that since 1891 the number of horses employed in this service has decreased by 162,000, or about 80%.

Total mileage of track	15,956
Capital stock	$828,547,285
Bonded debt	$525,949,928
Mileage of electric lines	13,556
" of cable lines	612
" of horse lines	1,351
" of dummy lines	384
No. of horses and mules	28,154
" of dummy engines	206
" of motor cars	20,777
" of passenger cars	28,621

On the steam railways the average haul was 23.24 miles per passenger and 115.96 miles per ton.

	1885.	1894.	1895.
Miles of steel rails	98,102	196,653	205,546
Miles of iron rails	62,495	35,266	28,652
Miles of track	160,596	232,919	235,198
Per cent. of steel rails	61.0	84.8	87.8
No. of locomotives	25,937	36,784	37,090

THE INVENTION OF THE ART OF LITHOGRAPHY, by Alois Senefelder, in Germany, in 1796, is to be celebrated in New York on Oct. 16 and 17. This celebration will take the form of an exhibition of all the different products of lithography, including prints from the earliest date and from all countries. Lectures upon the history and progress of this art by experts will also be given. Any one who can aid the committee in this laudable work by loaning specimens in their possession or by suggestions should communicate with the chairman, Mr. Joseph R. Keogh, 23 Third Ave., New York city.

ENGINEERING NEWS
AND
AMERICAN RAILWAY JOURNAL.

Published every Thursday at Tribune Building, New York.
Entered at the Post Office, New York, as Second Class Matter.

London Agencies: Kegan Paul, Trench, Truebner & Co. (Limited), Paternoster House, Charing Cross Road; Sampson Low, Marston & Co., (Limited), St. Dunstan's House, Fetter Lane.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00; *Single copies,* 15 *cents. To all other countries in the Postal Union, add* $2.08 *per annum* (4 *cents per number*) *to above prices for postage. No club rates allowed. Mailing addresses may be changed at will by sending both old and new address. We shall be obliged if subscribers who fail to receive their papers promptly will notify us without delay. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number* 326 *means that subscription is paid to the 32d week* (*that is the issue of Aug* 6) *of the year* 1896; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line agate measure. Want notices, special rates, see page* 22. *Rates for standing advertisements sent on request. Changes to standing advertisements must be in hand on Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The development of rail sections has always been an interesting subject for railway engineers and rail manufacturers, as in the early days of railways each engineer wanted to have a special section of his own on his own line, and each man had his own particular hobby as to rail sections. Within recent years a very close concensus of opinion has been reached as to the forms and proportions of rails, but on the less important branches and portions of many railways of any considerable age there are to be found various types of sections now obsolete. The development of the form of section on such roads is particularly interesting since it shows the changes that have been introduced under similar conditions, and in another column we give a set of the eight sections which have been used on the Denver & Rio Grande R. R., beginning with a 30-lb. rail in 1871, when the road was first commenced, and ending with an 85-lb. rail, which has been laid during 1895 and 1896. The oldest rails were of peculiarly round-headed section, showing evidently the influence of English practice, but more curious still are the two sections in which the sides of the head flare inward from the top, a form of section which was designed from wrong ideas and was but little used. The present rail section conforms practically to the type recommended by the committee of the American Society of Civil Engineers, except that the top corners appear to be of larger radius, while the sides of the head, instead of being vertical are slightly flared outward from the top. This latter practice is followed by a large number of railways, and is incorporated in the Dudley patented form of section now so extensively used. The set of sections which we illustrate in comparative form is a good example of the history of rail sections on individual railways in this country.

While the tie-plate is a decidedly modern invention it has already fully borne out the ideas of its designers and is now very extensively used, while its application is spreading very rapidly. Briefly this device consists of a metal plate interposed between the rail and the wooden tie, its purpose being to protect the wood of the tie from the cutting and abrading action of the rail, which action is more influential than any other in causing the destruction of the tie and rendering tie renewals necessary. The tie-plate is thus a species of tie preservative or protector, and is not to be classed with the old chairs and joint chairs whose office was to support the rail and hold it in position. It would seem at first glance as though such a simple thing as a tie-plate would not require much designing, and would not call for much theoretical consideration of the forces it has to sustain, but as a matter of fact, while the tie-plate is a small and simple thing enough in itself yet its efficiency may be very greatly increased by a little care in designing it with due regard to the work it is required to do. That this is so will be clearly understood from the perusal of a paper in another column. The manufacture of tie-plates is now one of the most important industries in the railway supply business, and while almost any form of plate is an improvement over the direct contact between rail and tie, yet it may readily be seen that there are opportunities for increasing the practical efficiency of the plates. The main objection to a simple flat plate is that it is impossible to keep it tight, so that there will be a continual movement of the rail on the plate and the plate on the tie, with a consequent admission of dust and moisture to cause wear and decay, and also a consequent clattering under traffic. Besides this, if the plate is thin and wide it will bend and buckle, while if made sufficiently thick to resist bending the plate will be clumsy and expensive. The question then is, how to secure a permanent connection between the plate and the tie, and this appears to have been most efficiently attained by making a plate with longitudinal ribs or flanges which sink into the fibers of the wood and are tightly held by them, while the size of the flanges is not such as to crush or split the wood. These flanges also serve to stiffen the plate and enable a thin plate to be used without buckling under heavy loads. The use of the tie-plates not only effects an improvement in the track, but also (at very little expenditure) effects a reduction in the expenses of track maintenance, since it enables soft and cheap durable timbers to be used for ties, as the timber is protected from the cutting action of the rail, and such cheap ties thus protected may actually last longer (and be thus more economical) than more expensive hard woods not thus protected.

The substitution of cable for horse-power on surface railways, and the consequent increased speed, reduced operating expenses and better service, certainly seems to pay in New York city, as is indicated in several directions. The Broadway cable-line, in its first year of operation, reported to the State Railroad Commission a gain of 25% in total traffic and a decrease of 20% in operating cost, or a total gain of 45%, as compared with the operation of this line by horse-power in the year preceding. The actual gain in passengers carried since then is not now at hand, but the Third Avenue cable-line was opened on Dec. 4, 1893, and the official figures for the year ending June 30, 1894, show a gain of nearly two million passengers carried over the average for the three previous years, though this report would include only about six months of cable service. How much loss of traffic might be charged to the delay in operation caused by the change from one system to the other it is impossible to state; but the undoubted and sudden increase in passengers after the cable was completed would seem to prove that the change was a popular one. That some other lines of traffic suffered by the changed conditions on these two cable surface roads is indicated in the lately published report of the Manhattan Elevated Railway Company to the State Railroad Commission. The report of this parallel and competing system is made up to June 30, 1896, and shows that the "total income" of elevated roads has steadily decreased since 1893, when the cable system practically came into competition. In this period the Manhattan has made considerable effort to maintain its traffic, and the growth of population in the northern section of the city has certainly not decreased. But the advantages of more rapid transit on surface roads, with no stairways to climb and somewhat less travel from the centres of traffic, has certainly had an effect upon the number of passengers formerly using the elevated system. The fact of the matter is that the cable surface roads are not only catching the short-haul passengers, but also many riding for long distanecs, who find the surface lines more convenient for their purposes and now fast enough to use.

Cuban, or rather Spanish methods of estimating upon and contracting for the execution of public works in that island are peculiar, to say the least. In a paper lately presented to the American Society of Civil Engineers, Mr. E. Sherman Gould, M. Am. Soc. C. E., describes the new water-works of Havana, and incidentally treats of the contract system prevailing there. After the preparation of the plans, an estimate must be made, down to the most minute details of the exact quantities of each class of work required. These plans, estimates and quantities, accompanied by a report, must then be submitted to the home government for approval; and after such approval any radical change found necessary during construction must first be submitted to the Cuban authorities, then to the home authorities, and a royal order obtained before anything can be done. While this may seem necessary, under the "paternal" form of government assumed by Spain towards its colonies, it is likely to be embarrassing to both engineers and contractors and certainly does delay execution. But another and seemingly very useless and objectionable feature of the system is the requirement that in quantity and cost each class of work must stand by itself. Consequently, if in the execution of the work any quantity, and, of course, the resultant cost, should fall short of the submitted estimate, this surplus is not available to make good any excess of quantity and cost in another piece of the same work; but a new appropriation for "extra work" must be carried through the network of red tape referred to, though there is actually an unexpended balance on hand. Another rule, which holds good in Spain as well as in Cuba, is that acceptance of the contract, after an examination of the plans and documents, makes the design virtually the contractors, and the contractor and not the engineer is responsible for all failure that may result from the plans. The only loop-hole of escape for the contractor is the filing of a written protest before commencing any work in which he deems the plans insufficient.

This system is certainly ingenious in its complicated difficulty, its multitude of authorities, enforced delay in execution, and in its disregard of the many contingencies which may make necessary some radical change in plan during the progress of the work. But it also indicates the tenacity of Spain's grip upon her colonies and how little she trusts them to attend to their own business. The proviso for shifting responsibility for the failure of plans, from the engineer to the contractor, reflects rather badly upon the confidence a Spanish engineer seems to have in the sufficiency of his own designs. And Mr. Gould shows in his paper that the original plans for part of the Havana work were insufficient. This reservoir was to be covered with groined elliptical arches of cement that were to rest upon granite columns made of three separate blocks of stone. The execution of this work was so difficult and almost impossible that the reservoir remains uncovered to-day, and plans for a safer and simpler covering were rejected. Under the peculiar Spanish laws regarding responsibility for plans, this failure to cover the reservoir must be charged to the contractor.

The use of springs for sources of public water supply is quite common in some parts of the country, notably in New England. The conditions governing the yield of springs have not been so carefully studied as those relating to surface sources. The reason for this, apparently, is that most springs have been utilized in this country where only comparatively small quantities of water are required. One or more springs have been piped to towns at the outset, and others have been added later, or other sources of supply sought, as the demands for more water arose. But even where only small water-works are to be supplied prudence demands that the available yield from a spring, or springs, shall be determined as nearly as possible, before adopted as a source of supply. The most obvious and common method of determining the yield is to make a gaging of the flow from the spring, but a single gaging, or a season's gaging is not sufficient to determine what may be expected through a series of years, even when backed by the assurance of the "oldest inhabitant" that the "spring was never known to run dry." Where the drainage area tributary to a given spring and the rainfall of a locality are known, the problem of yield, year in and year out, is very much simplified, but there still remains the governing geological conditions, especially the character of the material through which the water must flow and the relation of permeable and impermeable strata. These geological conditions may in part be determined by an examination of the surface, but cannot be completely learned without putting down borings or test pits. When all else has been decided there will still remain to be found the percentage of rainfall lost by run-off, by surface evaporation and by plant absorption and evaporation.

So far as we know, very little has ever been published regarding the available yield from springs. Far more has been printed on the yield of wells, a very closely related subject. With the growing demands for pure water supplies, the yield of our mountain and hillside springs, ever popular sources of supply, will become a matter of increasing importance, for however thoroughly it may be possible to purify water most people will prefer that which is naturally pure. In addition, a public water supply is already almost a necessity for the small villages of a few hundred inhabitants, and in some sections these may obtain, as many already are doing, ample supplies of clear, cool and sparkling water at slight expense, where a water purification plant might be considered as entirely out of the question, even if not actually so.

In view of the above facts we give a considerable amount of space elsewhere in this issue, to a paper by Mr. Louis E. Hawes, C. E., on springs as sources of public water supplies. Mr. Hawes has brought together some very interesting matter on this subject which we commend to those interested in the development of springs.

◆

The practically successful trial, at Portland, Me., of the Hargrave kite, as modified by Mr. Charles H. Lamson, is a marked step forward in solving the solution of aerial navigation. This kite, or aeroplane, was not only the largest ever successfully floated, but it also carried aloft the heaviest weight ever lifted with any similar device. Unfortunately the press accounts do not give the dimensions of Mr. Lamson's kite, other than to state that it took 15 men to carry it. The interesting point in the experiment, however, is the fact that a dummy weighing 150 lbs. was safely and steadily carried by this kite to a height of 600 ft. At this point a sudden gust of wind broke the retaining cord; but after sailing on for about half a mile further the kite descended as steadily and as easily as it ascended. Had a man been upon the kite he would have suffered no injury whatever. Those interested in Mr. Lamson's experiments may see a full account of his smaller kites in "The Aeronautical Annual," for 1896, edited by Mr. James Means, of Boston, Mass. This air-ship is practically made up of two rectangular cells, open at the parallel sides of the longest dimension. Each cell is jointed, or hinged, near the front and back ends, and these smaller hinged cells can be manipulated by levers so as to change the vertical direction of flight. Lateral steering is accomplished by shifting the weight to either side of the center, the vessel turning towards the loaded side. It should be explained that these two main cells are parallel to, but at some distance from each other, being connected by a light and strong framework. In the original kite there are no wings, or movable parts, other than the hinged ends of the main cells; and the especial features of this form of aeroplane are great steadiness in flight and unusual lifting power. The absence of intricate moving parts is especially advantageous, coupled with the general simplicity of form and construction, and further development on these lines will be awaited with interest.

GERMAN EXPORT METHODS.

In our issue of Aug. 13 we commented upon the growing interest in the United States in an increased export of our own manufactures and we also noted the more prominent American organizations now engaged in activily promoting the extension of this foreign trade. In connection with this proposed development of a practically new business it is profitable to study the methods of other countries which have resulted in commercial success, and among these other countries Germany is just now taking a very prominent place as a manufacturing and exporting nation. Methods which have built up a rapidly growing trade in German goods all over England, until lately almost without a rival in manufacturing for the rest of the world, are worth close attention.

A book lately published in England, entitled "Made in Germany," is creating a stir among the manufacturing classes in that country by bluntly proving, by statements and official figures, that England is fast losing her old position as the undisputed mistress of the world of commerce, and is no longer supreme even at home. The law requiring all foreign-made goods sold in England to be plainly marked as "made" in some other country, is having an unexpected reactionary effect. It is opening the eyes of British manufacturers and those interested in British industries to the present and rapidly increasing volume of goods "not made in England" and yet supplied to the consumers of that country. The label, "made in Germany" is appearing on a dangerously widening group of goods, and this means not only a shrinkage in the home market to English producers, but it also implies a perilous competition in the markets outside of Great Britain.

The author of the book quoted shows by figures from Parlimentary reports, that while the proportion per head of exported English products was about $40.24 in 1872, this proportion was only $27.70 in 1894. A reduction in the price of goods exported may account for a part of this decrease, but further figures presented give another and more potent reason in the German increase of trade in the same period. In 1883 the imports into England of goods manufactured in Germany were valued at $83,150,000; in 1893 the value of these German imports was $128,150,000, an increase of about 30 per cent. in ten years, and this in a country that in the near past had a practical monopoly in the supply of manufactured goods to a large part of the trading world.

While American manufacturers may not view this reduction in English trade with any overwhelming amount of sympathy and regret, the alleged causes of this decrease have a direct interest to them in any attempt to extend the introduction of their own products into other lands. And quite as interesting and worthy of study are the means by which Germany has succeeded in introducing her goods into England.

The author of "Made in Germany" frankly tells the manufacturers of Great Britain that under the prestige of the past monopoly of all trade they have grown too careless of the wants and demands of even English consumers. They make what pleases them best; adhere to out-of-date methods, designs and processes; and pay too little attention to the comfort and needs of their labor, a neglect which has a direct and injurious effect upon the quality and character of the product of this labor. In short, while the manufacturer has stuck to the rut marked deep by the wheels of another age of trade, the consumer is being educated to the advantages and possibilities of a more enlightened and intelligent treatment of an old subject. To make plain our meaning, we have only to contrast some of the commonest articles of household use as made in England and "made in Germany." In the one case we too commonly find old forms, clumsy and inartistic design and careless finish; in the other there is very generally a grace, lightness and beauty that can only result from careful study and intelligent attention paid to the minute details and the actual needs, use and appearance of the product, whatever it is. When this better and handsomer article is offered in the market for the same, or often at a lower price, it is not remarkable that the consumer will prefer it and buy it and that his neighbors will gradually do the same.

A late editorial in London "Engineering," treating of the rapidly growing competition of Germany and the United States with England in the Australian trade, incidentally illustrates the indifference of some English manufacturers in attending even to the wants of home customers. It seems that a prominent firm of engineers applied to a famous English tool-building establishment for some suggestions in the improvement of a certain class of machines which would tend to increase their output; and the application was coupled with the promise to purchase all machines from this firm if any substantial gain could be shown in the product. The tool-makers in question sent an aged foreman to look into the matter and he proved to be quite incapable of giving any advice of value. In despair, a German firm was then applied to with quite a different result. A bright young German engineer was at once despatched to the works in question who carefully and intelligently examined the machines in use, sent samples of the finished product to Germany and had the whole matter investigated by competent men there. The outcome was that the German firm supplied machines under a guarantee of saving effected that was much surpassed by the actual working of the tools themselves; and England lost what promises to be a very profitable trade. "Engineering," very properly, charges this English establishment with "sheer crass stupidity," but goes on to say that the workmen are to blame as well as the masters. With the object of keeping as many of their members employed as possible the trade societies resent the introduction of labor-saving machines as an injury; and Mr. Maxim relates that for months after the introduction of a special milling tool for machining parts of the Maxim gun, the men insisted upon taking as long to put the finishing touches to this part, after leaving the machine, as if the whole had been done by chisel and file. A German workman who could not speak English was finally put to work, and he accomplished six times as much work in one day as the Englishman did in 1½ days. These British workmen have yet to learn a fact well understood in American shops; and that is that one man can attend to more than one machine, and that experience shows that an increased and cheapened output usually so affects the demand that more, and not less hands are employed as the result of using labor-saving machines.

The cause for the success of Germany in England and the present rapid spread of German goods into English colonies and into other centers of trade once monopolized by England, is not a thing of yesterday, though the effects are only now being seriously felt. For fifty years or more Germany has been slowly but surely fitting herself to be a great industrial nation, by perfecting her system of technical education, now probably the most perfect in the world. She has studied the progress and methods of every other nation and she has trained men to improve upon these methods; she has sent her agents to all parts of the world that promised trade, and these agents have learned what will and what will not be acceptable to the prospective foreign consumer. She has trained men to extend this trade by establishing schools of trade and commerce, and by tabulating and making accessible all information that can be gathered concerning the products and conditions of the commercial world. She is in a position to meet the demands of other nations better than her old competitors, simply because she has studied them more intelligently. As showing the spirit which animates some of the larger German manufacturing concerns the author of "Made in Germany" notes that one German chemical establishment employs no less than fifty chemical specialists; not in the daily inspection of the products of this establishment, but engaged solely in experimental work and in the attempt to devise new and more economical processes of production. This, says our author, would be regarded as sheer waste of capital by the average British manufacturer; but he also notes that this particular German company pays dividends of 25 per cent.

While Belgium was the first of continental nations, in fact the first among nations, to establish a specially equipped school for the commercial training of young men, Germany soon followed, and has improved upon the Belgian methods. In these schools the study of languages is made a strong feature, and the student is compelled to carry on an "office correspondence" in German, French and English, and he must also select and be proficient in one other language, usually Spanish, Italian or Dutch. He is obliged to study the geography of foreign countries, their history and commercial conditions, and well-filled museums make him familiar with the vegetable, mineral and animal products of other lands. When to this early training is added the progressive spirit that seems to animate every workshop and counting house in Germany, and the wise liberality that is constantly furnishing the means for deeper experimental research into all that might benefit trade, it is little wonder that Germany is making herself felt as an industrial factor.

In this matter of languages the American manufacturer and his agents are notoriously weak, and before any marked success can follow in the extension of our foreign trade we must pay more attention to this important factor. As one of our consuls lately remarks, in discussing prospective trade with the South American States, no American maker of mining machinery would send as his representative to Cripple Creek a Russian wholly unacquainted with English; but the same man will distribute English catalogues among a Spanish-speaking people and send there a man who can only do business through an interpreter. As showing the part familiarity with a language plays in trade, the same consul notes that the United States does more business with 5,000,000 Canadians on its northern border than with the 14,000,000 Mexicans immediately to the South, or in fact with the 35,000,000 Spanish-speaking people in Central and South America. For trade purposes this population is as remote to the average American manufacturer as is China, simply because he does not know them nor their tongue and has not studied their needs and the possibilities of trade. Other nations have been wiser, or went there better equipped and they practically take business from our own doors that naturally belongs to us, and would be ours did we but meet the requisite conditions.

The secret of Germany's commercial success seems to be a careful and intelligent study of the best methods of manufacture and of the conditions, needs and prejudices of the trading world. As before remarked, she has long been preparing herself for the industrial war she is now waging by the technical education and commercial training of her young men. In methods of manufacture and in quantity, character and relative cheapness of products, American manufacturers need take no lessons from Germany; but they can profit by the manner in which Germany has sold her goods outside of her country and in properly equipping men to do this work. It would require a generation of time and a large expenditure of means and effort to accomplish this training by means of commercial schools. But the fact remains that to accomplish the task which many of our manufacturers have now set themselves, proper tools must be used, and the traditions of the past, applicable only to a home market, must be thrown aside. In this connection the several American organizations referred to last week are doing good work by making our manufacturers better acquainted with the conditions and possibilities of trade with other nations. This knowledge is a first requisite, but a second and all important one is the choice of proper agents and of effective methods of taking advantage of the possibilities uncovered. Here these organizations need the active co-operation and moral and financial support of every American manufacturer. And when this broad interest is once awakened we doubt not but that the means will soon be found for educating and supplying the required agents.

LETTERS TO THE EDITOR.

The Section of Electric Railway Tunnels.

Sir: In regard to the much-discussed question of the necessary sectional area in railway tunnels in cities, some late experiences on the Budapest underground railway give endorsement to the unusual dimensions adopted in Boston. The Budapest section was based upon the London tunnels; but it is found to be a great mistake to have two tracks in such a small tube. The ventilation is very bad and the air pressure is a serious trouble to the traffic, and, as experience proves, there may be other reasons for more liberal dimensions.

In one day lately the following accidents occurred on the Budapest railway: (1) A workman in stepping from one track to avoid a train was killed on the other track; (2) A conductor, leaning out to ascertain why the motorman was ringing the bell, was badly injured; (3) A car was set on fire in the tunnel by an accident to the grip-conduit and the six passengers only escaped through the coolness of the men on the burning car and the following car, the latter car being used to push the first rapidly out of the tunnel. Both motormen were badly injured. Some time ago an accident to the grip practically imprisoned in the tunnel, for some time, the Austrian Minister and a number of invited guests.

It is rather surprising that such accidents should occur in the operation of an electric underground railway; and they may be exceptional experiences that will not occur again in regular service. But the fact remains that they do happen; and it is evident that more room is necessary in the tunnel than just enough to pass the cars.

Yours truly, Fr. von Emperger.
Carlsbad, Bohemia, Aug. 2, 1896.

The three underground electric railways of London (one in operation, one nearly completed and one just commenced) are all designed with a separate tunnel, of circular section, for each track. The Budapest tunnel is rectangular, 19.7 ft. wide and 9 ft. high, with a row of columns in the middle. The Boston subway is also rectangular, 24 ft. wide and 15 ft. high, without a central row of columns, except on the four-track section, where the columns support the roof of a tunnel section 48 × 15 ft.—Ed.

Pooling Freight Equipment.

Sir: Referring to the editorial on my paper on the subject of "Pooling Freight Equipment," in your issue of Aug. 20, I am glad to have your expression on this matter, as "every little helps," and I am satisfied that the proposed scheme will effect a saving in expenses to railways of many millions of dollars per annum, as well as increase their earnings.

I note your remarks relative to a contemplated objection of putting equipment owned by "car trusts" into the pool. I do not see that this will make any difference for the reason that the trust cars will receive their prorata earnings according to their valuation in the pool and they will receive greater earnings on their equipment than at present; so it is to their interest to join in the proposed Co-operative Equipment Co. Yours truly,

Jos. R. Cavanagh,
Supt. of Car Service, C., C., C. & St. L. Ry.
Indianapolis, Ind., Aug. 28, 1896.

The Preparation of Bridge Specifications.

Sir: Your editorial on "Who should prepare specifications" is a very timely and valuable paper. If the suggestion contained therein, "that the engineer should consult with and profit by the experience of those whose province it is to carry out in practice the ideas which he originates," be followed it would inevitably lead to that most desirable end, a uniformity in best mill and shop practice. A uniformity of practice for the same grade and character of work and not a uniform specification for all grades and characters, without due regard for special duties, etc.; this latter would be manifestly unwise and unnecessary. Under the present method of each consulting and chief engineer preparing his own specification, incorporating his own particular hobbies, without regard to present practice, final costs or results, the manufacturer is compelled to work to numberless requirements; and in one bridge office there are to be found on file 60 different specifications for bridges alone. These special ideas often make it necessary to entirely change shop methods and practice, increasing cost, without any corresponding increased value or efficiency. Every manufacturer has had this experience.

It is with no desire to infringe upon the field of the consulting engineer and chief engineer that manufacturers prepare and publish specifications covering what they believe to be best practice in their specialties. Manufacturers and engineers should work together, and these specifications are prepared for the assistance and guidance of engineers in general practice, who have not the time or opportunity to give all the details of manufacture of each specialty the attention and study which are necessary to prepare a proper specification.

It would be very poor business wisdom on the part of any mill or shop, which cares for its reputation, to send out amongst its clients a specification which could be shown to call for poor grade of material or poor workmanship. I, of course, understand your remarks and suggestions as only referring to those manufacturers and engineers who have a pride in their work and name, are above any mere money getting, and who are continually trying to improve upon past practice, not only from their own experience but the experience of others in the same line. It would be useless to address those who resort to tricks and "wire pulling" to obtain business. Their practice is anything found necessary for the time being.

The field of work of the consulting engineer and the chief engineer of a railway or company is one which cannot be covered by the manufacturer; their work is mainly done before the contract comes before the manufacturer; they study the work in hand in all its bearings and relations, crystallize it into shape, fix the general requirements and divide it under its several classes of special work.

The contract is then in shape to be sent to specialists for prices. These special and detail specifications should not be prepared without conference with manufacturers unless the engineer by special training is entirely familiar with every detail of the work. If the letting can be confined to reputable concerns, it is desirable to give the manufacturer the opportunity of giving the engineer the benefit of his special experience and practice, not binding him to unimportant details at every point. The engineer is simply interested in final results; if these are up to his requirements and standard he should be satisfied.

In recent years there has been a tendency amongst parties who have work in view not to employ the consulting engineer or chief engineer, thinking to save this small expense, but to go direct to the manufacturer. This is poor judgment and a very unwise practice; it throws extra expense into every competition which the buyer must ultimately pay for; he will probably accept the cheapest bid made to him, and as the manufacturer has had no opportunity of judging of the merits of his design in connection with the surrounding conditions, it may be a very bad selection and cost more in the end. Engineering work of any magnitude should have the benefit of the disinterested investigation of a consulting engineer and the general features at least should be determined upon, before it is referred to the manufacturer. The practice above referred to is being discouraged more and more by the more reputable concerns, as it is not to their interest to do consulting work and they welcome heartily the supervision of any able and competent engineer and are glad to work to his requirements and specifications.

John Sterling Deans,
Chief Engineer, The Phoenix Bridge Co.
Phoenixville, Pa., Aug. 26, 1896.

SECTION OF WHEEL AND RAIL; C., M. & ST. P. RY.

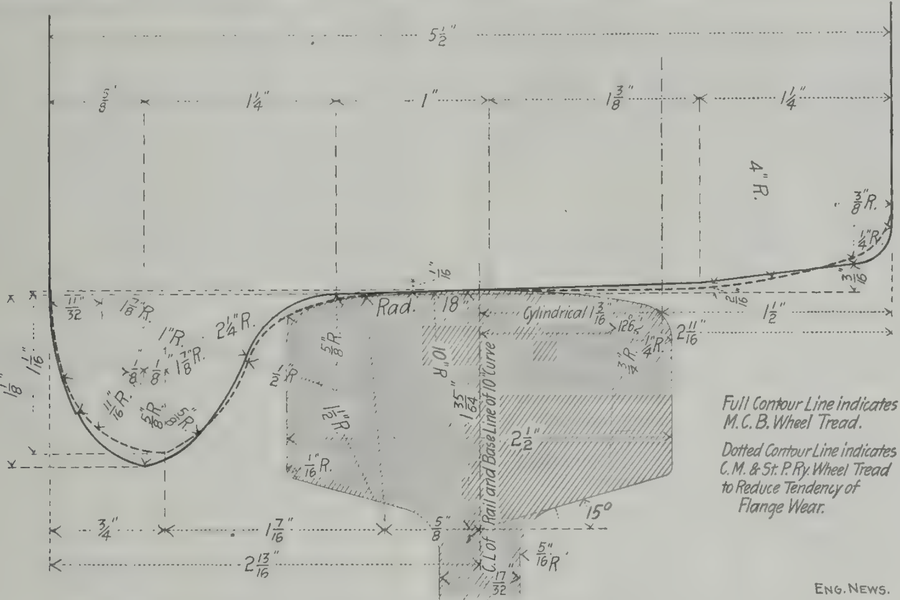
While probably a majority of railways in this country have adopted the M. C. B. standard section for carwheel tread and flange, this section is not universal, and the Chicago, Milwaukee & St. Paul Ry. has modified the section in such a way as to greatly reduce the flange wear. This section is shown herewith, together with the section of the head of the standard 75-lb. rail of the same road.

We are indebted to Mr. J. N. Barr, Superintendent of Motive Power, for a blue print, showing the C., M. & St. P. Ry. and M. C. B. sections of wheels, and we give below the remarks made by Mr. Barr at the recent convention of the Master Car Builders' Association, in discussing the question: "Is the present M. C. B. standard shape of wheel, tread and flange the best that can be designed for service."

> I have a blue print here on an enlarged scale, which reveals the fact that our present adopted dimensions won't go quite together. You have to squeeze them a little bit. In the present standard the fillet in the throat is ⅝-in. radius. We took and started from the center line of the rail with a 10-in. radius, gradually decreasing the radius to ½-in., and that gained in the throat, as shown in the difference between the dotted and full line, quite an amount of metal to wear off. In addition to that we gained the tendency (if the truck runs to one side) to run up on the fillet and guide itself away. The result has been a very decided decrease in flange wear, and that is one of the most serious sources of expense in the use of wheels—the rejections from flange wear. The tread is perfectly horizontal (or cylindrical) for 1 3-16-ins. outside; and from that point it passes off with a curve, which leaves the outside of the thread considerably easier and less projecting than in our present standard, which is a very good thing in going over frogs. These are minor points, but we feel that there is a good deal of money in them. We can very well see that after inspecting it; but the idea of enlarging the fillet here, so as to guide the flange away from the rail, instead of allowing it to run up against it, I think is a good idea, and the trains offer less resistance to the pull. The easing off at the outside has an important relation to frog wear and breakage of wheels.

In answer to these remarks Mr. Higgins stated that the tread of the M. C. B. wheel must necessarily be something of a compromise, from the fact that different engineers have different ideas as to proper rail section; and the rail section used on the C., M. & St. P. Ry. might be one the chief engineer of another road would not use. For that reason he did not think the association could do anything else than propose a tread that may be considered as a compromise.

In sending us the print of the standard rail sections (60, 67 and 75 lbs. per yd.), Mr. D. J. Whittemore, M. Am. Soc. C. E., Chief Engineer of the Chicago, Milwaukee & St. Paul Ry., stated that these were designed before the report of the rail committee of the American Society of Civil Engineers was promulgated, and had this report been issued sooner, it is exceedingly probable that the railway company would have adopted the Am. Soc. C. E. type of section, except in the item of top radius of the head. In the Am. Soc. C. E. sections this radius is 12 ins., but Mr. Whittemore prefers the 18-in. radius of the present rail, and it will be remembered that Mr. Whittemore has been a consistent advocate of flat-topped rails. The 75-lb. rail shown is 4¾ ins. high, with a base 4¾ ins. wide.



SECTION OF WHEEL AND RAIL; CHICAGO, MILWAUKEE & ST. PAUL RY.

UTILIZING SPRINGS AS SOURCES OF WATER SUPPLIES FOR TOWNS.*

By Louis E. Hawes, C. E.

Exactly why a spring appears at any particular place is not always apparent or subject to conclusive demonstration without investigation on an elaborate and expensive scale. The most plausible and comprehensive reason that is usually given is that "the ground water in moving down a valley by the action of gravity encounters an obstruction or dam in its course which forces the water to the surface, where it appears as a spring." There are other well recognized and fully as important factors which may be mentioned as follows:

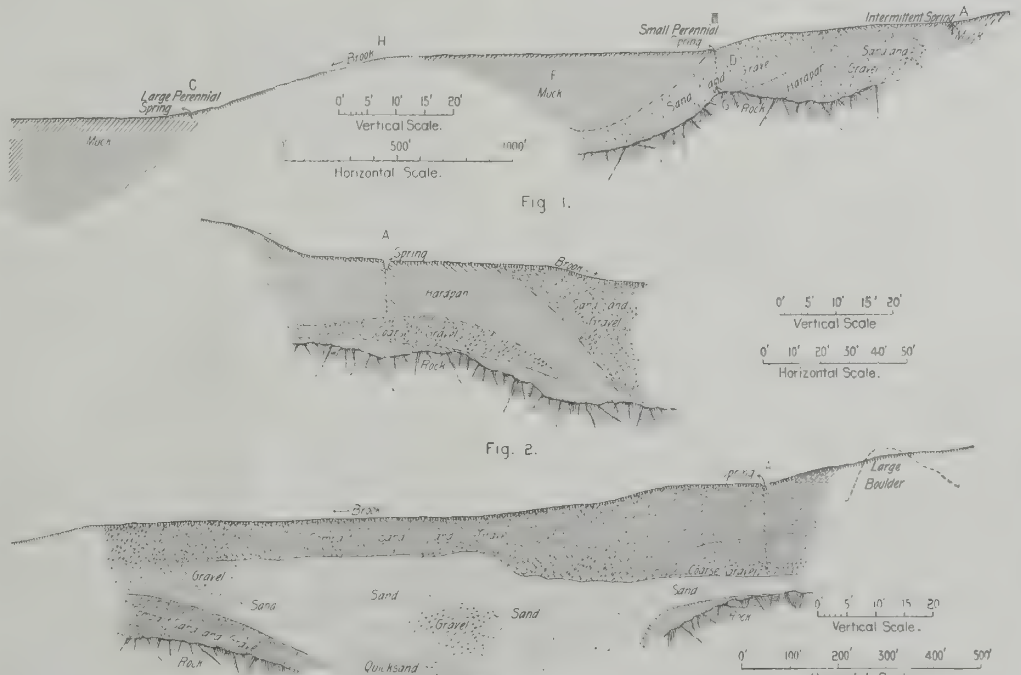
Differences in elevation between the absorbent or reservoir forming portion of the watershed and portions lower down, constituting the head; approach to the surface of the water-bearing strata or vein in which the water moves most rapidly, in consequence of the prominence of the bed rock or impervious strata below, or the rapid inclination of the surface above; the presence of boulders or ledge cropping at a location that is otherwise favorable, with the usual accompaniment of breaks and flurries in the stratification; and the perviousness of the overlying strata at a favorable point which offers little resistance to overcome the head.

As is very well known, the stratification of the glacial drift is decidedly varied and replete with abrupt changes; this is found to be particularly true where springs appear, so that in a consideration of the controlling influences little more than a statement of the general nature of the soil and a suggestion as to the main elements is possible without special data.

The relation of some of these factors in specific cases is shown by the accompanying diagrams which have been prepared from information gained through the aid of test wells and excavations in the regular course of practice, but without reference to its use for the present purpose. They represent the conditions in each place as closely as possible from the data available.

Fig. 1 is a longitudinal profile and section representing a portion of the upper part of the valley of Vine Brook in the town of Lexington, Mass. The watershed of the brook above the point marked C has an area of about ½ sq. mile, and above B, ¼ sq. mile. The valley has no well defined absorbent area of large extent above these points. The porous formation, of which there is a fair quantity, is distributed in small tracts on the main slopes and intervening undulations. Springs occur at the points marked A, B and C, and it is interesting to note their progressiveness as the area of the watershed increases, the one at A being an intermittent spring; the one at B, a small perennial, and the one at C a large perennial. Pervious material is represented as shown at D in the section, impervious as at E, muck as at F, and rock as at G.

The ground water in the valley above appears to be intercepted in its downward course by the impervious strata at E, causing it to find its way into the rock beneath, which is of a seamy, disintegrated nature, offering ample opportunity for the free passage of water and also permitting an outlet below at B, where the rock approaches nearest the surface and where the superimposed sand and gravel offers little resistance against the pressure that is acting upon the water.



SECTIONS SHOWING THE STRATIFICATION AT SEVERAL SPRINGS IN MASSACHUSETTS.

Fig. 1.—Longitudinal Section Through Springs in Upper Part of Valley of Vine Brook, Lexington, Mass. Fig. 2.—Section Through Strata at Porter Spring, Avon, Mass. Fig. 3.—Section Showing Formation at Colborn Spring, Needham, Mass.

The location of this spring appears to be determined also by a natural dam at H, some 1,300 ft. away, for the line of saturation between the two points is only slightly inclined, is practically at the surface, and but little below the elevation of the spring.

A marked feature of this profile is the succession of depressions containing muck deposits. The first one is 400 or 500 ft. long and 5 or 6 ft. deep; the second one about 1,000 ft. across and over 12 ft. in depth; while the third one is a half mile in extent and has a depth of 40 ft., or more. Geologists tell us that these depressions once formed ponds or lakes and that the muck has gradually grown until the basin has become entirely filled. Our observations and soundings show that this growth is in progress in many of the ponds, lakes and reservoirs now used for water supply purposes. Constant alluvium washings, debris, leaves, vegetable growths within the water and upon the bottom accumulate in the muck forming process that promises well for the ultimate conversion of the sheet of water into a meadow.

Fig. 2 is a sectional view at the location of the Porter Spring in the town of Avon, this state. The principal absorbent area is elevated from 15 to 50 ft. above the spring, is of considerable extent not far away, and the brook of the valley is about 450 ft. from the spring. The water issues at the point marked A in the figure and the principal factors determining the location appear to be the head or pressure and the interruption or determination of the strata carrying the water, which is occasioned by the impervious strata.

The water-bearing material is a coarse, reddish gravel 12 ft. below the surface, which disappears beyond the spring and is overlaid by a stratum of hardpan which also dips off a short distance away beneath the sand and gravel that follows. The bed rock is prominent, approaching within 16 ft. of the surface and dropping off below the spring, as in Fig. 1. As boulders occur in the upper strata, weak places were no doubt present which permitted the water under pressure to force its way through. It is significant regarding the head and usual tightness of the hardpan that when the well for utilizing the spring as a source of supply for the town was constructed, the walls were built up so as to store the water 3 ft. higher than before, which was accomplished and the water in the well stood 5 ft. higher than the surface of the meadow 75 ft. away; the site of the original spring having been previously sealed over.

Fig. 3 represents the formation in the vicinity of the Colborn spring at Needham, Mass., which is an unusually large spring. Although hardpan and clayey material exists in parts of the watershed, the major portion is of sand and gravel formation of various degrees of porosity. The principal area suitable for ground storage is ½ to ¾ mile from the spring and elevated 50 to 70 ft. above it. As shown in Fig. 3 the spring appears at A, where the bed rock is prominent, approaching within 19 ft. of the surface, and a very large boulder or ledge cropping occurs a short distance above, which as found by excavations apparently disturbed the regularity of the stratification.

The water bearing material is 14 ft. below the surface, and consists of a mixture of coarse gravel and disintegrated rock or boulders, with a finer material of a somewhat similar nature above and sand beneath, while the surface strata is compact sand and gravel. Small pockets of sand and clay were found irregularly placed at the spring location. In the valley below a decided depression occurs in the sub-formation, which is filled with sand and gravel, varying from quicksand to fair-sized gravel.

---

*Condensed from a paper read before the annual meeting of the New England Water-Works Association, June, 1896. The paper will be published in full in the Journal of the New England Water-Works Association.

The main factors in this case are the compactness of the sand and gravel immediately below the spring, the diminution or termination of the coarse strata or vein and the great pressure from the storage reservoir, combined with the nearness of the water bearing strata to the surface and the presence of malformations. There are no indications of influencing obstructions further down the valley, the brook in a distance of 1,400 ft. having a gradual fall of 8.5 ft.

The supply well constructed at this place permitted the water to overflow at an elevation 2½ ft. higher than the average level of the original springs, and ¾-ft. above the bed of the brook adjoining.

Where springs have been taken by right of eminent domain and the damages for so doing determined in court, very interesting questions arise as to their capacity, permanence, possibility of contamination, the value of water, relative value of the spring in question, rights of the owner to the exclusive use of its waters and even questions affecting its genuineness, as in a case recently tried in the Superior Court for Norfolk Co., Mass.

As no two cases are alike, and this one has been settled, no harm can result in describing some of the salient features. The trial resulted from a suit for damages in the sum of $25,000 for the taking by the Commonwealth of Massachusetts of the Blue Hill Silver Spring in the town of Milton, which is located within the Blue Hills Park Reservation. In making an examination of the spring, its surroundings and watershed for the purpose of estimating its value, it was found to be situated upon the southerly side of Great Blue Hill. The watershed has comparatively steep slopes, largely composed of a stony, rocky formation, constituting a quick shed without favorable conditions for producing springs. The spring-well is 43 ft. from the brook draining the valley, is 3½ ft. in diameter and 5½ ft. deep. There is no overflow, but the water moving in the same channel that supplies it issues from the ground 40 ft. away as springs.

The conclusion was early reached that this water was from the surface, escaping from the brook somewhere above the spring-well and finding a channel through the rapidly inclining stony formation to appear below as springs. Measurements and tests were made to determine this, and it was found that at a point on the brook 400 ft. above the springs the quantity of water flowing in the brook equalled the quantity issuing from the springs below, plus the quantity flowing in the brook opposite the springs; showing that the brook lost an amount equal to the flow of the springs, somewhere between the places measured and probably at a comparatively flat portion of the brook just below the uppermost point.

These measurements, together with results of a corroborative nature from other tests, demonstrated that the spring water was simply brook water a little earlier in the day, and from the nature of the intervening formation subject to practically the same influences. However, both the brook water and the water from the well were excellent in quality at the time of the examination, and possibly more suitable for table use than many waters used for that purpose that come from permanent deep-seated springs.

In considering the possibility of utilizing a spring as a source of water supply for a town, the question of purity and freedom from possible future contamination having been settled satisfactorily, considerations of the size or flow of the spring, its permanence, seasonal variations, the area and nature of its watershed and its location and relation to other sources of supply naturally follow. To serve as the entire supply a spring must be of unusual size or the number of inhabitants to supply correspondingly small; when neither of these conditions is fulfilled except in a moderate degree, a spring favorably situated may be made a valuable adjunct to a supply from another source, either as an increase to the existing quantity or for the purpose of imparting an improvement to the quality, which is usually the result of such an admixture.

The number of springs that may be found in nearly every town in New England is almost surprising; no less than seven of fair size were examined by the writer in one town during preliminary investigations for a water supply, so that one almost invariably hears of certain springs that "never go dry," to use a common expression, that are suggested as suitable for public use. Most of them are either too small, isolated or unfavorably situated to be available for a town supply; but all have their enthusiastic admirers, and it is not to be wondered at, for with a spring are ever associated thoughts of an ideal drinking water.

When the possibility of having such water for every day domestic use becomes a reality, to draw it from a faucet like common river or pond water in a large city, and at an expense of less than 0.004 cts. per gallon instead of from 3 to 10 cts., as is paid for table water by the jug or carboy, it is a matter for congratulation, and the community possessing it is indeed fortunate.

The size or flow of a spring depends upon the area of the absorbent surface, the storage capacity in the ground, the head or resultant velocity of the flow, and the capacity of the channels through which the water passes, but it is always subject to direct variation with the rainfall. The main storage reservoir may be near or distant from the spring, but seldom or never surrounds it and is always above and usually at some distance away. The water reaches its outlet through the channel offering the least resistance, which may be a very porous strata, a particularly open portion of such strata, fissures in the rock or through the broken stone resulting from the disintegration of rocks and boulders. Where the water moves most rapidly in such channels it constitutes a vein, whose course may be very irregular and which is, therefore, often difficult or impossible to find from the surface.

The capacity of a spring in its normal condition can be readily ascertained by measuring its natural flow; if these measurements are continued at regular intervals over long periods of time, including seasons of extreme conditions, the seasonal variations will be determined. Such records are rarely kept, however, their importance seldom being realized until the spring is utilized and the normal conditions changed.

The capacity of a spring after its resources have been developed, or rather the capacity of the well or wells constructed for its development, differs materially from its normal capacity. The channel through which the water finds its way to any particular spring may be only one of the various outlets of the storage reservoir; the other outlets may appear at the surface as springs in other parts of the watershed of the stream draining the valley, or may continue underground in other courses to ponds and rivers below. Consequently, when the water is drawn down at any spring to a lower elevation than that at which it naturally appears, the head is increased, causing a corresponding increase in velocity of the inflowing water, which results in a greater discharge.

When the surface of the water is first lowered this increase in quantity may be partly ascribed to the amount stored in the immediate vicinity of the well; after a while this is exhausted, but the changes in inclination of the lines of saturation have become far-reaching and water hitherto moving in other channels is diverted by the changed conditions and follows the new inclination. If the draft is continued the storage reservoir will be affected, its surface lowered or inclination changed and other outlets will lose a part or the whole of their flow, which is thereby contributed to the well being drawn upon. The latter condition was illustrated during continued pumping from the Needham well while in process of construction, with occasional interruptions. The flow of the Hicks spring half a mile away was diminished perceptibly and the action of the hydraulic ram affected, which was particularly noticed to occur when the pump at the well was in operation.

TABLE I.—Yield in Gallons of Porter Spring, Avon, Mass., 1889 to 1895.

	1889.	1890.	1891.	1892.	1893.	1894.	1895.
Rainfall (Chestnut Hill reservoir), ins......	54.79	50.21	49.63	42.27	46.71	38.17	45.93
Daily average for the year..................	.....	12,982	39,945	41,168	55,124	59,728	61,921
Maximum pumping,[1] gallons per 24 hours ..	.....	27,752	44,484	82,807	81,455	101,313	75,945
Maximum for one day, gallons....................		77,589	84,811	120,045	122,974	143,970	135,531
Time pumping max. quantity, hrs. and min.	.....	2:30	2:30	3.25	.......[2]	4:40	.......[2]
Total gallons pumped during year................		4,738,609	14,580,106	15,026,291	20.120,272	21,800,682	22,601,234

[1] Ten consecutive days. [2] While painting stand-pipe.

Note.—The yields given above are from the pumping records after beginning to utilze the springs. Observations of the natural flow in 1889, before beginning to pump, showed a natural flow in gallons per 24 hours, as follows: Minimum, 43,056; average, 49,680; maximum, 70,992; equivalent to 18,133,200 gallons per year. A 53-hour continuous test of pipe wells showed a yield at the rate of 243,000 gallons in 24 hours.

TABLE II.—Yield of Colburn Springs, Needham, Mass., 1890 to 1895.

	1890.	1891.	1892.	1893.	1894.	1895.
